back and of the extremities. Two weeks after the onset, ophthalmoplegia was complete in both eyes and a left seventh-nerve paralysis had developed which resulted in inability to close the left eye. Voiding had also become difficult. The facial-nerve lesion then slowly regressed so that 2½ weeks later the patient could close the lids to within 2 mm. of each other. Six weeks after the onset of the disease, the right eye could be adducted 20 degrees and the left eye could be adducted 15 degrees and could hold fixation better than the right. Vertical movements were almost nil. Eight weeks after onset, the patient was suppressing in the right eye and fixing with the left, and monocular adduction had largely returned. Pupils had returned to normal and accommodation was sufficient to read 8-point type at 13 inches unaided. Convergence remained nil. A severe weakness of all muscles of both hands remained. Both deltoids and triceps remained paralyzed. There was left wrist drop and bilateral foot drop, worse on the left. Six months later the right medial rectus was functioning; the left medial rectus was paretic, and scarcely any motion had returned to the vertical muscles.

Convergence was nil and the wrist and foot drop remained severe.

The patient received a total of 2,820,000 units of penicillin, 12 gm. of sulfadiazine, and 1,350 cc. of convalescent polio serum.

COMMENT

The external recti, last of the extraocular muscles to become paralytic, were also last to show any improvement. Convergence was early lost and not regained. Recovery from internal ophthalmoplegia was rapid. The seventh-nerve palsy occurred two weeks after onset of the illness, but recovery was more rapid than that of the third-, fourth-, or sixth-nerve palsies. Diplopia was an early symptom and extraocular-muscle involvement was prominent, well in advance of spinal-cord symptoms.

SUMMARY

Although ocular complications of acute anterior poliomyelitis are not uncommon, ophthalmoplegia is rare. A case of bilateral complete ophthalmoplegia with left seventh-nerve palsy is presented.

METHOD FOR RESTORATION OF HUMAN ORBITS FOLLOWING NECROSCOPY ENUCLEATION*

M. HARVEY JOHNSON, M.D.
Detroit, Michigan

The field of keratoplasty and sight restoration is relatively new but in its short existence has attracted widespread interest. It is evident that the continued progress in this science depends, in a very great measure, upon the proficiency in obtaining eyes for pathologic study as well as for corneal transplantation.

It has been our experience while working with the Wayne University Eye-Bank, which was under the direction of Dr. Parker Heath, that the education of the public to give their eyes, at the time of death, depends to a large extent upon the assurance by the physician that the orbit will be restored to a normal outward appearance.

The object of this study is to present an approved, simplified technique for restoration of the human orbit. There will be no external evidence of alteration if the orbital cavity is prepared in accordance with the following procedure.

MATERIAL

Hemostat, cellulose cotton, sealer solution¹ ("Stix," Gold Crest Chemical Cor-

poration,[†] 1063 Jackson Avenue, Long Island City, New York), eye caps (Edward S. Butler Company, 33 Otolaya Terrace, San Francisco, California), are the materials needed.

PROCEDURE

The first step is to control the leakage from the terminal branches of the ophthalmic artery as they enter the orbit through the narrow apex of the muscle cone. This is accomplished by thoroughly crushing the tissue at the apex of the orbit with the aid of a hemostat. The optic nerve will also require crushing if it has been severed near the globe.

The capillary type of leakage is adequately controlled by sealer solution which is applied with cotton in a thin film over the orbital walls and permitted to dry. This is sufficient to seal the vessels and to withstand the usual pressure of injection of embalming solution.

The remainder of the orbital cavity is then filled with a cotton ball of suitable size followed by insertion of the eye cap. (The author wishes to acknowledge suggestion and aid given him by the Department of Mortuary Science, Wayne University, Detroit.)

BLACKBOARD CORNEA FOR TEACHING

ANDREW DE ROETHH, SR., M.D.
Spokane, Washington

The teaching of clinical ophthalmology is rather handicapped by the small size of the eye. When not a few individuals but a whole class has to be instructed, the use of the blackboard, slides, or moving pictures is imperative. When pathologic conditions of the anterior segment have to be demonstrated on the blackboard, one is handicapped by trying to draw on a plane, that is in two dimensions, conditions which are three dimensional.

To overcome this difficulty, a blackboard cornea for teaching purposes was devised. This is a cornea made of plastic material.* The measurements are 15 times the size of a normal-sized cornea, except in thickness. This gives a horizontal diameter of (15 by 11.75 mm.) 17.6 cm., a radius of (15 by 7.7 mm.) 11.5 cm. The scleral overlapping at the upper and lower limbus is indicated by a frosted crescentic portion 12-mm. wide at the 12- and 6-o'clock positions. The thickness of the blackboard cornea is only 3 mm. instead of (15 by 1) 15 mm., to make it light.

When demonstrating a condition of the anterior segment of the eye, a circle is drawn around the border of the cornea while this is held against the blackboard. The cornea is then removed, and the iris and pupil and the pathologic condition under discussion are marked on the blackboard. The cornea is fastened against this drawing with a 3.75-cm. (1½-inch) wide piece of Scotch tape placed across its upper edge. This makes it possible to lift the cornea by its lower edge if further draw-

ing is necessary in the iris plane or on the posterior surface of the cornea. Now the pathologic condition of the cornea can be marked. Grease pencils of different colors have to be used, because chalk does not write on plastic. These marks can be removed with warm water and soap, or more easily and faster with cleaning fluid

Figs. 1 and 2 (de Roethh, Sr.). Blackboard cornea. Fig. 1. Large central corneal scar with superficial vessels. Pencil pointing to a vessel. Optical coloboma of the iris between the 3- and 4-o'clock positions. Fig. 2. Interstitial keratitis with two bundles of deep vessels. Dull corneal reflex due to epithelial edema.

(for example, energine) or plastic remover. The demonstration is more life-like on a white board or frosted glass.

Figure 1 shows a central corneal scar with superficial vessels. There is an iris coloboma at the 3- to 4-o'clock positions and a sharply outlined corneal reflex.

Figure 2 demonstrates interstitial keratitis with very dull corneal reflex and two bunches of deep corneal vessels which were drawn on the posterior surface of the cornea.

The blackboard cornea facilitates the demonstration of pathologic conditions of the anterior segment. In addition to this cornea of plastic material, colored grease pencils, 1½-inch wide Scotch tape, and cleaning fluid (energine) to remove the markings are all that are needed to operate it.

LEONTIASIS OSSEA

DR. EDNA M. REYNOLDS presented Mrs. C. B., aged 52 years, as a case of leontiasis ossea which is limited to the sphenoid bone on the right side. The patient gave a history of a severe fall at about the age of six years in which the right side of her face was struck against a curbing. There was no apparent deformity until seven years ago when she hit the right eye on the knob of a chair in leaning over to pick up papers off the floor. After this injury, the right eye became prominent. In 1940, she went to Colorado General Hospital because she found that she could not see with the right eye.

When she was first seen in July, 1944, the right eye showed proptosis with limitation of movement laterally. Measurement with the exophthalmometer showed 28 mm. for right eye and 19 mm. for the left. (The same readings were found at Colorado General Hospital in 1940.) Vision was reduced to light perception.

The vision of the left eye without correction was 20/15+ and the eyeground was normal. An X-ray study of the skull was made by Dr. Harmon Brandenburg, who made the diagnosis of leontiasis ossea. The X-ray report was as follows: "Primary involvement of the sphenoid on the right side, with lamination of frontal bone; closure of the sphenoid fissure and foramina including the optic, causing blindness of the right eye and pro-

tusion of eyeball due to enlargement and pressure from behind."

Leontiasis ossea is the name given to the condition of hyperostosis of the facial and cranial bones. The disease has also been termed megalocephaly and hyperostosis of the skull. Since there was no tendency to malignancy, no treatment was advised. In these patients there is a tendency toward slow healing, and in this case, there had been no advance in the condition in a 4-year interval.

The patient was seen again in September, 1946. At that time, there was no apparent change in her condition and X-ray pictures showed no advance in the condition. Enucleation of the right eye for cosmetic purposes has been considered but declined by the patient.

CAVERNOUS OPTIC ATROPHY

DR. R. W. DANIELSON presented A.M.K., a 73-year-old clerk, who had come to the office about a month previously complaining of failing vision in both eyes of several years' standing. He had been to an optometrist recently who was unable to improve his vision. He had had no pain or other symptoms of glaucoma. On examination, uncorrected vision of the right eye was 20/100, and of the left eye, 20/15. This could not be improved with correction. The media and fundi were normal except that there was a deep cup in the temporal four fifths of each disc. The lamina cribrosa was not plainly visible. There was no overhanging of the edges of these cups. However, the appearance of these cups was such that one would offhand have certainly made a diagnosis of glaucoma. The perimetric field of vision with a 3-mm. white test

object showed only a small strip near the point of fixation on the 180-degree meridian of the right eye. In the left eye there was an almost concentric contraction down to about 20 degrees. The tension on each eye was 20 mm. Hg (Gradle-Schiøtz) and, after dilatation with homatropine for two hours, the tension was still 20 mm. Hg in each eye.

The patient was placed on pilocarpine. The next day the intraocular pressure was 13 mm. Hg in each eye. This pressure was taken on several subsequent days and was never found to be above 20 mm. Hg, except on one day following a provocative water-consumption test when the pressure of the right eye rose to 24 mm. Hg. On this day, pilocarpine had not been used, the water test was repeated using pilocarpine at the same time. In this instance, tension of the right eye did not increase after consumption of large amounts of water, but tension of the left eye went from 20 mm. Hg to 24 mm.

This appeared to be a case of so-called low-tension glaucoma until it was finally decided to make an X-ray study of the patient's sella turcica. Surprisingly, the X-ray report revealed changes in that region probably secondary to meningioma. The case was referred to Dr. Charles Freed, a neurosurgeon, who verified clinically the probability of an intrasellar tumor and recommended exploration.

Discussion. Dr. Freed discussed the case and gave a résumé of the clinical signs and symptoms of the various types of lesions that can occur in the sellaturcica region.

Dr. George Filmer told of a young woman patient who complained of slowly progressive blurring of vision. Peripheral fields were normal, although there were small central scotomas in each eye. Spinal fluid was normal. The case resembled early optic neuritis. She developed right homonymous diplopia and, during an ex-

ploratory craniotomy, a large cystic Rathke's pouch was found. The patient died. This cavernous atrophy of the disc very closely resembles glaucoma cupping, even to the overhanging veins.

Dr. T. Van Bergen asked if normal eyes gain in pressure after much water is imbibed in a short time. Dr. W. H. Crisp asked if local sclerosis could cause these changes. Dr. Freed added that any visual loss is an indication for surgery in these cases because this loss is irreparable; otherwise, X-ray therapy might be attempted. These explorations are not dangerous and should be done whenever reasonable doubt exists.

Dr. Danielson, in closing, said that changes in the normal eye probably do not occur after much water intake so that water imbibition serves as a good provocative test in glaucoma. Local sclerosis could resemble this case, but there now seemed no doubt that this was a case of cavernous atrophy.

DIABETIC CATARACT

DR. RALPH JORGENSEN presented L.H., a boy, aged 18 years, who complained of sudden loss of vision over a period of three days about three months before. A general practitioner found him to be diabetic, and he was sent to Colorado General Hospital. Examination revealed bilateral, advanced, subcapsular cataracts with no fundus details visible. Blood-sugar level was 260 mg. percent, and urine sugar showed a 4+.

DISINSERTION OF RETINA

DR. RALPH JORGENSEN presented D.R., a 38-year-old man, who had noted that vision of his left eye was suddenly becoming poor about three months before. This decrease in vision had continued. There was no history of trauma. He was recently sent to Colorado General Hospital where examination revealed the

retina to be disinserted over the lower half at the ora serrata extending from the 4- to 7-o'clock positions. No tear was seen. Field studies showed absence of the superior half of the field except for a circle of about 10 degrees around the fixation area. Vision now is: R.E., 20/15; L.E., 20/70.

DR. BENJAMIN FRIEDMAN, *president*

TECHNIQUE AND COMPLICATIONS OF
KERATOPLASTY

DR. R. TOWNLEY PATON presented (with motion pictures) this subject. He stated that corneal transplantation, although not difficult for the experienced surgeon, should first be practiced on animal eyes. Over the years, experience has shown that the judgment needed in the selection of cases is learned only by those who have done many of these operations. Ideal cases for operation are relatively rare, and it is for this reason that it is best to have one eye surgeon do a lot of these cases rather than have many surgeons who perform only one or two keratoplasties a year.

The visual results in certain selected cases for operation are often dramatic. Postoperative complications increase in direct proportion to the size of the graft. Grafts of at least 6 mm. should be used in keratoconus cases, and only those cases in which there is a central corneal opacity or in which contact lenses cannot be tolerated should be operated upon. Postoperative complications in suitable cases are few. Many cases are operated, whose prognosis is bad to begin with. Our

present knowledge has reached a point where we can select the operable cases with a fair degree of certainty.

Donor material. The eyes of newborn and premature infants are not satisfactory because the corneal tissue is more delicate and too malleable which causes more post-operative edema; also, these eyes do not keep as well.

Operative technique. Cutting the donor eye first gives the operator an opportunity to get the feel of his trephine. The trephine must be absolutely sharp.

The transplanting of corneal tissue for the treatment of scarred corneas has proved successful in many carefully selected cases. The operation itself is not of recent origin. Many cases were operated upon before 1900, but successful results have only been reported in recent times. Types of cases favorable for operation include those in which the scarring is central and not too dense and those in which no increased intraocular pressure is present. The presence of a large number of blood vessels in the cornea may often spoil the result of the operation. There must not be any active corneal disease present or any disease of the surrounding tissues. Uveitis of recent occurrence may be an exception.

Cases in which the scarring is limited to a small central area of the cornea, not over 5 mm. in width, and the scarred area is surrounded by healthy corneal tissue, entirely free of vessels, and the eye is otherwise considered to be normal give the best, and often the most startling, visual improvements. Visual improvement from 20/200 to 20/20 or better may be expected.

Keratoconus has not, in Dr. Paton's experience, given the best visual results for several reasons. He wished to report on only those cases in which the vision cannot be improved by means of glasses or contact lenses beyond 20/200. Because of

the dangers of using larger transplants, the operation is difficult.

NEW TYPE ORBITAL IMPLANT

DR. NORMAN L. CUTLER presented this subject with motion pictures. He stated that this implant for use in enucleations is composed of a plastic sphere with a gold ring for muscle attachment and a gold face plate into which fits a metal pin on the prosthesis. This gives a positive mechanical contact between the prosthesis and the implant.

An average movement of the prosthesis of 70 degrees, horizontally, and 65 degrees, vertically, is obtained. In addition, there is instantaneous movement over the shorter ranges. Some patients who can converge preoperatively are also able to converge postoperatively. The film showed postoperative results of this type of implant.

Discussion. Dr. Byron Smith said that past experience, with heterogeneous tissue transplantation and integumentary tolerance to foreign bodies justifiably causes us to accept with skepticism any advance in this field. In retrospect, it is difficult to understand why we have been so retarded in a more logical approach to the proper camouflage of ocular prostheses.

Nonirritating foreign bodies, completely submerged in tissues, are relatively well accepted by the human organism. Partially submerged foreign material as described by Drs. Ruedemann, Cutler, and Hughes, defies the laws of nature and has a tendency to nullify our previous concepts of surgical principles. The discouraging cosmetic results and complaints of the patients suffering from the presence of the early Ruedemann implant are not uncommon to some of us. The complex secondary surgery required in the removal of such an implant is, unfortunately, familiar to few ophthalmic surgeons.

At a meeting of the American Ophthalmological Society, in 1945, Dr. Wendell Hughes presented the details of a partially submerged vitallium integrated implant. He suggested that an oval, rather than a spherical, contour is an advantage in preventing rotation of the implant. Rounded rather than square corners at the contact between the implant and artificial eye was described as an asset in maintaining hygienic conditions in the orbit containing the prosthesis.

Erosion of glass by the fluids of the eye socket is frequently encountered. Individual allergy to plastics and plastic eyes is a recognized affliction. It is assumed that erosion and allergy of partially imbedded vitallium is less than might be expected from plastic.

Since I am not acquainted with Dr. Cutler's surgical resident, but have had an opportunity to observe Dr. Hughes, it is probably unfair for me to remark that implantation of the device into the muscle cone and Tenon's capsule is a major surgical undertaking. The modified Mules implant of vitallium described by Dr. Hughes for insertion through the sclera beneath the superior rectus muscle by the Burch technique of evisceration is technically simple and immediately effective. The narrow peripheral, perforated disc of remaining cornea securely surrounds the zenith of the implant, heals rapidly, and has been the source of no sensitivity.

In closing, I would like to ask Dr. Cutler a few questions:

1. What is the duration of time required for you to execute the implantation of the prosthesis you have initiated?

2. Have you encountered local tissue allergy to the implant in any of the cases you have treated?

3. Have you observed any postoperative deviation or rotations of the implant on its anterior-posterior, vertical or horizontal axis?

Dr. E. Waldstein asked whether it is necessary to use general anesthesia.

Dr. Barnard asked if the implants could be removed by the patient, and if so how frequently, and how difficult it would be to replace them.

Dr. Bernard Kronenberg asked whether it would be worth while to use the oblique muscle in this procedure.

Dr. B. Friedman asked if it were possible to reoperate old cases.

Dr. Cutler, in closing, replied that there are other techniques which are being used that are of interest. He remarked that since there is so much interest being shown at present in the use of implants, some day something adequate will be discovered for a heretofore inadequate procedure. He expressed the hope that there would be sufficient improvement to standardize the procedure in enucleation. The limitation of space in which a prosthesis has to move makes perfection impossible.

Dr. Cutler's procedure takes about one hour. It is rather tedious, but does not require anything unusual in experience and skill. The fact that these operations were done by eight different men in the first two dozen cases, indicates that it is quite routine. In regard to local allergies, he stated that he had not seen any local reaction from plastics. Some of the patients were observed for six months and none of them developed any tropia. Some of his patients have been seen by other ophthalmologists and no cases of tropia have been reported.

As regards doing the operation under general anesthesia, Dr. Cutler said that it could be done, but that he is inclined to use sodium pentothal on most middle-aged patients.

As for removing the eye and cleaning it, contact-lens suction discs have been used. The length of time it can be kept in the socket varies a great deal. Some individuals can leave it in for 1 or 2 months without removing it.

In regard to the oblique muscles, nothing has been done, since that would add quite a bit to the operative procedure. As for reoperating for removal of glass balls, one of these operations had been done and it is planned to take preoperative and post-operative motion pictures of some others. In these cases all that is done is to make a cruciate incision through the conjunctiva and roll Tenon's capsule around the ring and suture it into place. There is no particular advantage in isolating muscles. In this case the technique worked without difficulty.

TRAP-DOOR OPERATION FOR GLAUCOMA

DR. LOUIS A. LEHRFELD spoke of Lieut. Col. H. Herbert of the Indian Medical Service, who had contributed many splendid articles on the surgical treatment of glaucoma from 1903 to 1934. Dr. Lehrfeld described (with motion pictures) the well-known "trap door" or flap operation, which had been devised by Dr. Herbert initially for absolute glaucoma but which was later used for all forms of primary glaucoma.

Using a narrow Graefe knife, an incision is made in the sclera, 2 mm. long and 1.5 mm. from the corneal margin in the lower outer quadrant of the globe. From the two ends of this small incision, two shorter forward cuts are made to the limbus by turning the edge of the same narrow blade forward and sawing carefully to avoid puncture of the iris. Thus, a small rectangular flap or tongue of corneoscleral tissue is made.

A modification of the technique is presented by making the trap-door in the silent or safe area of the sclera, in the region of the pars plana ciliaris. This site is selected, because there can be no damage to the ciliary, no damage to the lens, or no damage to the iris. Heretofore, all operations for primary glaucoma were in the region of the corneoscleral junction, the danger zone of the eye, where sur-

gery in itself may so complicate the glaucoma as to prove fatal to the eye.

Dr. Lehrfeld said that no attempt is being made to substitute the Herbert operation for the well-known and accepted surgical procedures for glaucoma. The modified Herbert operation is offered as an additional, elective surgical procedure, based on the principle of securing a continuous and slowly draining aperture in the sclera away from the danger zone and in the silent area of the eyeball.

Discussion. Dr. B. Friedman asked whether, in the event that the tension is not controlled by the operation, this would lead to a staphyloma of the operated area. Would leaving such a large opening in a vulnerable spot subject the eye to rupture from external pressure?

Dr. Lehrfeld, in closing, replied that in 20 cases which he had operated, no such occurrences had taken place.

Bernard Kronenberg,
Secretary.

VISUAL ACUITY TESTED WITH MOVING
OBJECTS

DR. ELEK J. LUDVIGH said that, in view of the absence of any information on this subject, it was deemed advisable to conduct an investigation of this subject, particularly since the eyes are so often and critically employed under these conditions.

The first and simplest type of motion to be investigated was that of simple rotary motion of the test object. This was obtained by viewing variable sized Snellen test letters through a prism of various strengths rotated so that letters appeared

to travel about in a circle in a plane perpendicular to the line of sight, monocular observation being used. Visual acuity was reduced by increasing the angular velocity and by the speed of the moving test object. The conclusion was that when an eye follows an object moving about in a circle in a plane perpendicular to the line of sight, the acuity will be reduced either by reason of the eye being unable to move sufficiently rapidly or by reason of the inability of the individual to change the innervation to the various eye muscles sufficiently rapidly, or both.

When the visual acuity was tested with the eye following an object moving in the horizontal dimension, an angular velocity of 170 per second was required to reduce the vision to 20/200, whereas when the test object was rotated, an angular velocity of only 62 per second was required. This was to be expected since experiments with the rotating test object showed that inability to change innervation rapidly was a factor and that conjugate lateral movement is apparently a relatively simple movement to innervate.

Dr. Ludvigh then outlined further proposed lines of investigation with the test object moving in various ways and conversely with the test object being stationary and nystagmus being present. In the latter situation initial experiments had been started by making short exposures of letters to see if the visual acuity was increased or decreased in a case of nystagmus, but conclusions could not be drawn. He said that he would welcome any further suggestions on this problem.

In the discussion that followed, the use of the stroboscope in the study of nystagmus was suggested, but Dr. Ludvigh thought that the swing of the nystagmus was not sufficiently regular to employ it. In reply to questions in regard to head movements, Dr. Ludvigh said that they had not been permitted in the experiments as yet because it would be superimposing

another factor on the problem of eye movements. However, he thought that the fixation in following moving objects would be more accurate with head movements permitted, inasmuch as the head would take care of the grosser portions of the movements, which would necessitate the eyes following only a little.

PROBLEM OF OPHTHALMIC EDUCATION

DR. W. J. B. RIDDELL of the University of Glasgow, Scotland, gave the main paper of the evening. He said that in recent years great thought and planning have been devoted to various aspects of medical education. Certain factors have contributed towards this activity in the United States and in Britain. There has been a desire on the part of the Universities and Medical Schools to raise the standard of the undergraduate course, and this has led to a demand for more trained graduate instructors. This activity has been more marked in America where the ratio of teachers to students is very high compared to Europe. Facilities for study in other medical schools and the provision of necessary scholarships, free from routine clinical work, have increased the interest aroused in graduate training. The number of such opportunities is many times greater in America than in Britain.

The medical courses in the two countries differ in important respects. The British student graduates as a Bachelor of Medicine and Bachelor of Surgery (M.B., Ch.B.) from his University after a course lasting five or six years; a certain proportion, around 15 to 20 percent, proceed to the higher degree of Doctor of Medicine (M.D.). It is not possible to obtain the latter degree without possession of the two former ones. The graduate wishing to specialize, particularly if he aspires to a position on the staff of a teaching hospital, must also obtain a Fellowship from one of the Royal Corpora-

tions. These corporations are medieval guilds which have continued throughout the centuries in a modified form.

It is possible to obtain a Fellowship in which ophthalmology forms part of the examination in Scotland and Ireland. New regulations for the English Fellowship are projected in which ophthalmology forms the principal subject of the final examination. A primary examination on the basic series of Anatomy, Physiology, and Pathology will remain common to all candidates.

The diploma in Ophthalmic Medicine and Surgery (D.O.M.S.) is obtained by examination and is of somewhat similar scope to the certificate of the American Board of Ophthalmology. It was introduced mainly to raise the general standard of ophthalmic practice and to assist the public, insurance societies, and similar bodies in recognizing medical men qualified to carry out ophthalmic examinations.

One of the dangers attending the elaboration of highly trained specialists is that there tends to be an excess of experts in certain chosen centers who are unwilling to leave the academic or scientific atmosphere in which they have been reared. In so far as this happens it is a reflection upon the teachers; they have failed to produce an all round craftsman capable of performing his chosen job of work apart from elaborate equipment and buildings. There is no doubt that a great loneliness descends upon the young surgeon during the years immediately following his period of residence and research in a big center. This lasts until he finds his feet in a new area, but the isolation may be relieved by the stimulating effect of small visiting surgical clubs and associations. Organizations of this type were dear to the heart of Osler, whom it will be recalled started at one time to become an ophthalmic surgeon. Our loss has been the great gain of general medicine, and

we may speculate upon what he would have contributed to ophthalmology had he devoted his genius to it.

There are certain developments in ophthalmic teaching which can be regarded with some misgiving. Many students have to spend time on acquiring an examination knowledge of subjects in which they have no real interest and no practical acquaintance. Some planners seem unable to appreciate a vital educational principle which was expressed so clearly by Sir Richard Livingstone, Master of New College, Oxford, a few years ago. "The principle is that almost any subject is studied with much more interest and intelligence by those who know something of its subject matter than by those who do not; and, conversely, that it is not profitable to study theory without some practical experience of the facts to which it relates."

Dr. Riddell has great hope and confidence that ophthalmology will continue to develop powerfully in both England and America. In Britain they envy our libraries, clinics, and research facilities; they are proud of their own clinical traditions and are conscious of their scientific failings. In no special branch of medicine is a sense of historical perspective so well developed as in ophthalmology. The great British clinical school of the 19th century was followed by the dominant position gained by Germany at the beginning of the century. Britain now turns towards the New World for inspiration and finds it in full measure.

Discussion. DR. EDWIN DUNPHY said that an English friend once said to him (and Dr. Riddell touched upon it tonight): "The greatest bar to misunderstanding between our two countries is our common tongue."

In continuing, Dr. Dunphy said that because of the fact that we speak the same language, many of us on either side of the Atlantic might feel that we should

have the same customs. As a matter of fact, they differ tremendously in many respects. I am sure that Professor Riddell has been just as mystified by many of our medical customs as I was with the British system when I lived there in 1943 and 1944.

Professor Riddell has outlined some of the similarities and differences as they appear to him. As an American living in the British Isles, one of the things that impressed me most was the absence of the State Board examinations.

Another notable difference that impressed me was the extremely young age at which the British medical men can begin to practice. There are no age requirements for matriculation in the medical school, a man will often enter at the age of 17 or 18 years, and will graduate at the age of 22 or 23 years. Practically 15 or 20 percent of these men have an A.B. degree.

Although such a system lightens the economic burden, it would perhaps seem to us that the advantage must be weighed against a certain lack of maturity in starting to heal the sick, and also, possibly, a lack of training in the liberal arts. That might seem so, but, as a matter of fact, the difference is not as much as you would think, because I am quite sure that the average young Briton, aged 17 years, is much more matured than the American of the same age.

Coming to ophthalmology—both Britain and America are faced with the problem of not having enough ophthalmologists. I think that is true in this country more than in Britain. That is, we need ophthalmologists to take care of all the ophthalmic needs of the population.

For instance, in the United States, as you all know, 75 percent of the refractions of the general population are done by optometrists. Some may not think that is a very bad thing, and others think it is too bad. Also here in this country, we

have 7000 ophthalmologists, and we need, as was said, about 300 new ones a year to make up for the loss in death and retirements. We were training, as of December, 1941, 180 new men and women a year, and now we are qualifying about 250 a year. Therefore, we have a deficiency in the residency training of ophthalmologists. Certain other candidates are being trained by means of short courses and apprenticeships, and are being certified by the American Board of Ophthalmology, if they pass the necessary examinations. The American Board has not reduced the standards of the examinations, and, as far as I know, does not intend to.

In order to meet this shortage problem, we can either develop more residencies to train more men to become top-flight surgical ophthalmologists, or else we can train more medical ophthalmologists by means of postgraduate courses. If we adopt the former plan, and if it were possible to double or triple our residencies, we would have to cut down on the amounts of surgery and on the individual instruction of surgery, and there would not be enough to go around. On the other hand, if we greatly expand our postgraduate system courses to take in hundreds and hundreds of new men, we may be able to develop enough medical ophthalmologists to become good sound diagnosticians who can compete with the optometrists in serving the refraction needs of the country, leaving the residency training to the men who do the surgery.

In an editorial, I read some comments upon the difference between the American and British outlook in this teaching program: "The aim of the American side of the Atlantic is a very thorough and complete training of a relatively few high-grade specialists. On the British side, the aim and basic conviction of a large number is for a shorter time, leaving it to the

initiative of the few to obtain for themselves the final gloss and polish of academic distinction."

The American Board of Ophthalmology stated that short courses are an abomination, unsound pedagogically, and productive of a poor grade of practitioners. Nevertheless, Lancaster feels that we should be realistic about the situation, and face the fact that there never will be enough residencies to take care of the demand. Therefore, he feels that perhaps it is better to give short basic courses to all who apply, trusting that enough good men will be given their chance to make good and go ahead to make up for the undoubtedly great number of poor men that will be taken in. He feels that these basic subjects can be taught by lectures, quizzes, and reading, and thus large groups can be instructed at one time. Those who cannot obtain residencies should be placed as apprentices in older doctors' offices. How such a scheme will work remains to be seen. I think it is too soon to judge it.

Here at Harvard Medical School, we feel that laboratory work is essential to the teaching of basic sciences. This type of teaching can best be done with relatively small groups and by full-time research men rather than clinicians. This basic training should be followed by clinical residencies, with a form of instruction continued by clinical men. This is the policy that we are maintaining. I admit that it doesn't solve the main problem in the slightest. Perhaps the solution may lie in the development of ophthalmic technicians such as has been suggested by Parker Heath, who is with us tonight. Such a group could be developed in the colleges—not right away, of course, but on a long time program—giving about two years of training in physics, chemistry, biology, physiology, mathematics, and optics. This two-year training period would be followed by perhaps a one year

training in the hospitals, in refractions, and so forth. Such a person could then be employed by the ophthalmologist and work entirely under his supervision. Perhaps such an ophthalmologist could employ two, three, or four, and the load would be correspondingly reduced.

I don't know the answer to the problem. I do not for a moment doubt the sincerity of purpose of those who believe in training large numbers and in so-called medical ophthalmologist short courses. Personally, I mistrust the wisdom of such a course. A number of men so trained by this course will undoubtedly develop into very excellent ophthalmologists, I know, but I fear that we may flood the country with some very mediocre material.

DR. PARKER HEATH said that he was very much interested in the various angles which had been discussed. Since ophthalmic technique was a little hobby of his, he was glad to say something about it.

The point is that optometry itself is a dying profession. There were relatively few going into optometry before the war, and the present increase in optometry is apparently a by-product of the educational impulse which is going around the country.

Ophthalmology has not met the needs and qualifications, so far as the demands are concerned in the medical field. We have had this tried and true method of training people whereby every doctor had a nurse or someone else trained to help him with the onerous part of the practice. The extent to which these assistants can go is dependent on the ability to teach of the man in the office. That is, the assistant can do refractions, assist on smears and cultures, assist in the office and have a real, not quasi, professional relationship which can be described as an ophthalmic associationship. The basic principle involved is the distribution of medical care. The public isn't accurate in its classification of teachers and practitioners. Only

by roundabout methods do they find out where to go and what to do about their optic difficulties. So, the boards are established to help in this matter—State boards, ophthalmic boards, and so on.

The problem is one of medical care and medical distribution of this care. Any thing we can do to help shift the care and cover a wider field is going to help solve the problem.

I put forth this idea, which isn't necessarily mine (it might be an old idea in a new dress) of the ophthalmic associate—one who serves under medical aegis all the way through, who is bound by the same medical standards maintained under the same medical code, not answerable to a board outside but under medical ethics to the American Board of Ophthalmology.

We seem to be living a one standard or preaching a one standard practice, but at the same time to be living a two standard existence, because there are medical ophthalmologists and surgical ophthalmologists, and the greatest need is for medical ophthalmologists. I would say why not have two kinds of diplomas? This would be one solution, so these people who are medical ophthalmologists can have their place in the sun and be a recognized group. They prefer their work to that of the surgical ophthalmologists.

The second suggestion is to furnish a group of ophthalmic associates who can be educated in colleges as far as humanities are concerned. Technical training can be given by medical men themselves.

DR. S. JUDD BEACH said that the first thing that he had to say was in regard to the course that Dr. Lancaster has supervised and organized. If Dr. Lancaster were here to speak for himself, Dr. Beach felt sure that he would agree entirely with Dr. Dunphy that the thing to aim for is the type of course given at Harvard rather than the short courses which have been arranged to fill in during the in-

terval when nothing else is available. A course is obviously better when it is conducted along didactic lines, followed by a proper laboratory and clinical program. The type of course that Lancaster has arranged cannot fairly be called a short course, in the sense that the refresher courses, for instance, are short. There are short courses at the George Washington University and in Rochester, but they are entirely different.

Concerning the men who have come up to the Board for examinations the records of those taking the study council courses have been, I won't say all that is to be desired by any means, but very much better than those of the men who have taken a refresher course, feeling that it would fit them for a Board examination.

Dr. Beach expressed to Dr. Riddell the indebtedness of the Board for making the suggestions which led to the formation of the Board. These suggestions came through Dr. Jackson and were based on the type of examinations which were given in Britain. In the second place, Dr. Lancaster's course was copied in some part from the courses given at Oxford, which Dr. Riddell has mentioned tonight and which he had a part in organizing.

In the third place, Dr. Beach thought that the very important suggestion which Dr. Riddell had made ought to be considered, and that was that medical ophthalmology should be perhaps more thoroughly worked out in the examinations by, as he said, neurologists and the like for examiners. Actually we should have a second surgical certificate from the Board, to be given to those men who can do surgery. Dr. Beach said that the young men who come into our office tell him that they find it very much more difficult to perform good refractions than operations. He is not at all sure but that the second and advanced certificate should

be given in medical ophthalmology.

DR. RIDDELL (in closing): You have mentioned how easy it is for a medical man to practice in Britain, that he needs only register to protect the public. That is nothing—any layman can operate with a razor blade if he wishes to. If the patient dies, that is too bad. If he is a registered medico, he's O. K. Similarly, a quack cannot sue for fees. Apart from that, it is a free country.

You also mentioned that students start earlier. The average age is 18.3 years. As for myself, I skipped off to the Navy. They start in the University with biology and physics.

In regard to refractions—it is the same in Britain as in America, 75 percent are done by the optometrists and opticians.

A great deal of the training is done by apprenticeships and bedside teaching. That's one of the reasons why the universities in Britain are opposed to technical training—they are not keen on building up technical training in the universities. For some reason, there are no professors, or hardly any specialized professors in the universities. That's just the way we do things.

This business of ophthalmic technique is a very difficult one. We will probably do something similar to what Dr. Heath outlined for you tonight. I wouldn't be surprised if we were to have supervised ophthalmic technicians for Scotland.

Medical ophthalmology is an enormous thing in itself. It can be very fascinating. There have been surgeons who have abandoned the surgical in order to devote all their time to ophthalmology. There is a larger question of proportion in these things that has to be considered. That is how I think about it—we must have technical assistants (call them optometrists) in an equal proportion or balance for the particular community or state which has to be served.

Directors: LAWRENCE T. POST, President; WILLIAM L. BENEDICT, Vice-President; DONALD J. LYLE, Secretary and Treasurer; WILLIAM H. CRISP, FREDERICK C. CORDES, DERRICK VAIL.

Address original papers, other scientific communications including correspondence, also books for review to *Dr. Derrick Vail*, 700 North Michigan Avenue, Chicago 11, Illinois; Society Proceedings to *Mrs. Katherine F. Chalkley*, Lake Geneva, Wisconsin. Manuscripts should be *original copies*, typed in *double space*, with wide margins.

Exchange copies of medical journals should be sent to *Dr. F. Herbert Haessler*, 324 East Wisconsin Avenue, Milwaukee 2, Wisconsin.

Subscriptions, application for single copies, notices of changes of address, and communications with reference to advertising should be addressed to the *Manager of Subscriptions and Advertising*, 700 North Michigan Avenue, Chicago 11, Illinois. Copy of advertisements must be sent to the manager by the fifteenth of the month preceding its appearance.

Author's proofs should be corrected and returned within forty-eight hours to the *Manuscript Editor*, *Mrs. Katherine F. Chalkley*, Lake Geneva, Wisconsin. Twenty-five reprints of each article will be supplied to the author without charge. Additional reprints may be obtained from the printer, the George Banta Publishing Company, 450-458 Ahnaip Street, Menasha, Wisconsin, if ordered at the time proofs are returned. But reprints to contain colored plates must be ordered when the article is accepted.

OPTOMETRY AND OPTICAL DEVELOPMENTS

In his testimony before the Committee on Military Affairs, House of Representatives, held in Washington on July 3, 1945, at a hearing on a bill to establish an optometry corps in the Medical Department of the United States Army, Mr. Leslie R. Burdette of Salem, Oregon, past president of the American Optometric Association, included the following remark in his statement: "Parenthetically,

I should like to add that these highly developed instruments which are so necessary for the correct diagnosis of visual defects have in most instances been invented or considerably improved by physicists and optometrists not by physicians." In refuting this claim, Dr. Alan C. Woods, professor of ophthalmology, Johns Hopkins University School of Medicine, stated: "They (the optome-

trists) have made extraordinary claims regarding the apparatus that they have designed and perfected. In answer to that claim, I can only tell you that in the Wilmer Institute, which I believe is one of the best equipped in the world, I do not know of one single, solitary piece of apparatus in the whole institution that owes its genesis to optometry."

Legalized optometry is only 39 years old, dating from 1908 when the first optometry law was passed by the State of New York. It was instigated by Charles F. Prentice so that he could legally charge a fee for his services. Like the creator of Frankenstein, the father of optometry found that his brain child developed otherwise than he would have wished, and in his memoirs decried the unwarranted assumption of the title "doctor," pseudo-scientific pretenses, aggressive commercialism, and dubious practices.

At the same time that optometry made its advent, ophthalmology had reached a high degree of development, especially in the field of physiologic optics and optical instruments. The progress through the ages had first been very slow, and to the mathematicians we owe the fundamental laws of optics—Euclid, Alhazen, Snell, Gauss, Euler, Listing, and Lambert. The astronomers—Galileo, Airy, Kepler, and Hooke—gave us the telescope and the spherocylindrical lens, clearer conceptions of the function of the human eye and vision, and the concept of the minimum separable. The learned clergy-scientists—Roger Bacon, Sheiner, Mariotte—contributed the first publication on spectacles, the demonstration of accommodation, and the knowledge of the blindspot. The physicists—Newton, Fraunhofer, Brewster, and Wheatstone—discovered the nature of color and invented the stereoscope. The physiologists and psychologists—Mueller, Weber, Koenig, von Kries and Weber—clarified the facts of visual sensation and

adaptation, giving interpretive significance to the data of anatomy, histology, and biochemistry. Much of this, and particularly the pioneer works of Young and Helmholtz, paved the way for the monumental work of Donders that appeared in 1864 and at last placed refraction of the eye on a scientific basis. On this firm foundation, numerous ophthalmologists have contributed to the superstructure—notably Tscherning, Nagel, and Duane. The problems of orthoptics and ocular motility, first emphasized by Javal, numbered among its eminent devotees Stevens, Savage, Howe, and Maddox.

Meanwhile the optical armamentarium rapidly increased. In 1784, Benjamin Franklin invented bifocals; in 1804, Wollaston designed the meniscus lens; in 1839, photography was simultaneously discovered by Daguerre and Talbot; in 1851, came Helmholtz's epochal ophthalmoscope. In 1857, Jaeger provided reading charts; and in 1862 Snellen devised the modern refraction chart. In 1867, Green introduced the improved astigmatic dial, modified by Lancaster and Verhoeff, now used. Cuignet invented the retinoscope in 1874; Javal and Schiøtz, the ophthalmometer in 1880. Of the numerous optical instruments since developed and in daily office use, none of which, parenthetically, have been devised by optometrists, probably the most essential are Jackson's cross cylinder, Gullstrand's slit-lamp and corneal microscope, and Lloyd's stereoscopic scotometer.

The optical companies with their scientific staffs in applied optics have made and are making notable contributions. Von Rohr popularized vertex refraction and punktal lenses; Clifford Brown furnished the valuable duochrome test; and worthy improvements in bifocals have been made available.

The history of the development of contact lenses is liberally coated with

the names of physicists from Sir John Herschel, 1845, to Müller, 1887, and Professor Abbe of Carl Zeiss, 1888. Fick, ophthalmologist of Zürich, in 1888, coined the term "contact lens." Dallos of Budapest made the first impressions of the eye with negocoll, followed later on by Obrig, an optician. With much fanfare, Feinbloom, an optometrist, and Beacher, an optometrist, hopped onto the band wagon. There is now a considerable commercial value in the business of fitting contact lenses.

The authors of the leading textbooks that are used in the schools of optometry—Southall, Sheard, Fincham, Emsley, Swaine—although teaching in schools of optometry are not optometrists at all, but are physicists specializing in the applied optics of refraction.

The writings by the practicing optometrists in the various journals of optometry are quite another story. Here we see glasses with invisible tint, cures for color blindness, the improvement of vision without glasses à la Bates, muscle and prism exercises for the cure of myopia, revolving colored lights for the cure of many ocular diseases, unknown and unnamed, expensive nonsense for remedial reading, and visual training couched in gobbledegook language. All of these practices betray an ignorance or disdain of the fundamentals of physiologic optics, anatomy, physiology, and pathology of the human eye. Could it be possible that Mr. Burdette, O.D., was referring to these items in his remarks about "highly developed instruments?" If so, then the ophthalmologist will gracefully concede him the honors.

Derrick Vail.

OPHTHALMIC DISPENSING

Perhaps "optical dispensing" would be a rather more logical term; but there may

be a certain utility in recognizing that the great State of New York has adopted the caption title in its dealings with the subject. The implications of either term are sufficiently broad to touch the whole optical trade, even indirectly the wholesale manufacturer of lenses, although more particularly the frame maker and dealer, the retail optician, some jewelers, the refracting optician or optometrist, and the prescription optician. Many physicians who dispense their own prescriptions would come within the heading, although exempt from special laws dealing with this practice.

The ophthalmologist who relies upon the work of retail opticians rather than upon his own personal activities in optical dispensing learns to have considerable confidence in the judgment and, as suggested by Post in his editorial in the June issue of this JOURNAL, even the advice of such opticians as to technical details concerning frames and lenses. But the ophthalmologist may also find cause to be disgusted at the inadequacy of training of other optical technicians with whose work he comes into occasional contact.

It is a source of satisfaction to know that there exists within the ranks of the optical trade an active movement toward improvement in the standards of optical dispensing. Ophthalmologists who realize the importance of the subject may profitably study the April-May issue of *Guildcraft*, the organ of the Guild of Prescription Opticians of America (1947, volume 20, number 6).

Among other items, that issue contains the following material. First, the New York State Department of Education announces its initial Examination in Ophthalmic Dispensing, held May 8 and 9, 1947, under the special provisions of the Education Law adopted by the State of New York in 1946. This law requires that ophthalmic dispensers practicing as

such on July 1, 1947, must hold certificates in that capacity issued by the Department of Education, unless duly licensed to practice medicine or optometry in the State. Subject to certain exceptions as to those already engaged in such practice, candidates must have completed a year of study in a "school of ophthalmic dispensing registered by the Department as maintaining a satisfactory standard," or must have had at least one year of acceptable training and experience in ophthalmic dispensing under the supervision of an ophthalmic dispenser, physician, or optometrist.

The next item in the quoted issue of *Guildcraft* describes a technical course offered by the Institute of Applied Arts and Sciences of the New York State Department of Education, including periods in mathematics and physics; in "ophthalmic materials" (including the history of spectacles, development of ophthalmic lenses, the manufacture of lenses, and various details with regard to glass, grinding and polishing materials, metals, alloys, and plastics used in the optical trade); in prescription laboratory technique; in lens surfacing; and in the verification and inspection of spectacle products. Further, the student is instructed in the principles of refraction and the phenomenon and theory of vision and the physics of light; including the principles involved in various well-known ophthalmic instruments. Finally, he is given a definition and outline of "services rendered by each group in the eye-care field."

The fourth item in the April-May issue of *Guildcraft* is the noteworthy address by Benedict, mentioned in Post's excellent editorial in the June, 1947, issue of the *American Journal of Ophthalmology* (page 765). It will have been observed from that editorial that the Junior College of Rochester, Minnesota, on the in-

itiative of the Ophthalmological Division of the Mayo Clinic and of four major trade organizations, has already created a two-year course in "Opticianry" (a new term coined for this purpose), and that it is proposed to follow that course by at least a five-year apprenticeship before the candidate is permitted to apply for certification as "Master Ophthalmic Optician."

No doubt opportunity will be afforded later to compare this plan with that announced from New York, and indeed with other such educational schemes which may be expected to develop in different parts of the United States. It will be interesting to consider how such plans are likely to influence the development of shop and counter work in optics, as well as the trade and professional relations between ophthalmologists, optometrists, and the general public.

When, in 1827, the astronomer Airy calculated the strongly compound myopic astigmatic error of his own left eye, with its "major axis" at 35 degrees from the vertical, he went to an Ipswich optician named Fuller, who ground the necessary concave spherical curvature on one side and the concave cylindrical on the other.

Fuller no doubt was a man of moderate schooling but of long apprenticeship to a master optician. In those days it was the common thing for technical training to be obtained by many years of apprenticeship. The apprentice first ran errands, fetched materials, delivered finished work, cleaned out the workshop and guarded it in his master's absence, and was gradually, and in the course of time, intrusted with the execution of mechanical details, so that he became more or less thoroughly intimate with the principles and practice of the artisan to whom he had been bound by contract.

The same sort of approach to expertness was found in the studio of the sculp-

tor or painter artist or in the printing establishment. The teaching of medicine or of the "apothecary's art" long went through somewhat similar developments, and it is only something like three quarters of a century since the great majority of this country's physicians depended, at least for a large part of their training, upon the guidance of a preceptor to whom they occupied a relation somewhat similar to that of the apprentice in other crafts.

A comparable approach to the optician's craft may be found today in opticians' stores and workshops. However, there is bound to be a variation in the extent to which the modern optician concentrates either on the craft of making lenses or on the commerce of selling them to the public. More and more the non-academic approach to any field of activity is recognized as open to the criticism that it leaves gaps in the pupil's knowledge. The counter optician may have had little to do with the actual grinding of lenses. On the other hand he must himself be a craftsman of a sort in the fitting of spectacle frames and also in checking the accuracy of the shopman's work. As in most lines of mechanical activity, it is pretty certain that some individuals will know more about one aspect of the craft or trade, others more about other aspects; and that few will be equally adept or learned in all details.

In such wide variations of individual experience, training, and skill lies a sound basis for demanding standardization in the technical education of those who minister to the public's optical needs. Many of those engaged in the optical trade have scattered their energies over too wide a field of related but more or less distinct responsibilities. They attempt to be at the same time diagnosticians, mechanics, and salesmen. It is well to remember that the Guild of Prescription Opticians itself represents a healthy tend-

ency toward concentration on the dispensing of optical goods.

To what extent will the general public gain by the movement now fostered, in somewhat different shape, on the one hand by the New York Board of Education and on the other hand by the Mayo Clinic in coördination with a group of optical organizations? The type of training at first selected by those who, after passing through high school or college, decide to establish themselves in one branch or other of the optical trade, will depend partly, as now, on financial considerations, and partly on the miscellany of circumstances which make for choice of job or career among the general population. Some will start without vision or ambition for the future and will develop plans as they go along. In this feverish age, perhaps not many young tradesmen will be induced to plan for a two-year course of training which may, after a further five-year apprenticeship, lead to certification as Master Ophthalmic Optician. It may be suggested that such a certificate would have to compete with that of "Doctor of Optometry," a title which is the professional goal of many of today's optical dispensers.

Granted that a move for educational standardization in this practical line is desirable, it is likely that many such as now enter the retail optical trade in a rather casual fashion will continue to do so, and that of these at least a fair proportion will still seek to obtain a state license to practice optometry.

Whereas the New York Department of Education has decided to call the trade "Ophthalmic Dispensing" (which for practical purposes we may consider as identical with "Optical Dispensing") and another group of educators, including Dr. William L. Benedict and Charles Sheard, Ph.D., propose to call it "Opticianry," may it not be better to adhere to a single

title, and of the two titles to use that which is the more adequate and logical? The term used by the New York State Board of Education appears to cover the subject rather well (unless "Optical Dispensing" is preferred) and to be logical in form, whereas the entirely new term "Opticianry" is of somewhat dubious etymology and vague significance. The two may of course persist side by side. What's in a name?

W. H. Crisp.

BOOK REVIEWS

KERATOPLASTY AND TISSUE THERAPY. By V. P. Filatov. Moscow, State publications of medical literature, 1945. 232 pages. 233 illustrations.

This book, by the chief of the Ukrainian Experimental Institute of Ophthalmology, best known for his pioneer work in keratoplasty and for his recent development of a new method of therapy with preserved animal and plant tissues and their extracts, gathers in a monograph the formerly published data of the Institute, and adds the material accumulated during the war in the various military hospitals. When the Institute in Odessa was abandoned because of the Nazi invasion, the staff of the Institute was assigned to various military hospitals where the doctors had an opportunity to pursue their clinical studies. In 1942, the Institute was reopened in Tashkent.

The preface to the volume is as revealing as some of the technical expositions. As his catechism of faith, Filatov declares that only optimism and therapeutic activity can lead to progress. He believes that every organism holds hidden within it potentialities for recovery, if one could but release them. One must therefore never give up the exploration of therapeutic resources, and when forced to ad-

mit defeat, one must leave the patient with a hope and expectation of some new discovery, which may bring relief. "Pessimism at the bedside and in science is fruitless, and not to it belongs the future." This philosophic attitude helps to understand what otherwise, because of the skepticism incident to accurate scientific evaluation, might appear as an unrestrained flight of an unscientific imagination.

The volume actually consists of two monographs, which Filatov combines for the purpose of historical perspective, inasmuch as tissue therapy was the outgrowth of his experience with keratoplasty. The first part, dealing with keratoplasty, reviews in detail the clinical experience based on about 1,000 cases, and the experimental and research data in connection with it. Filatov introduced the use of cadaver cornea into keratoplasty, and through the study of eyes enucleated after successful transplantations, demonstrated that the transplant forms a true union with the cornea of the host, and is not merely a scaffold for the ingrowth of corneal elements from the recipient's cornea. It was also shown that the cornea is preserved best without fluids at a temperature of 3°C.; under these conditions the oxidative processes are continued in the cornea and lens; and despite autolysis the preserved cornea continues to exhibit cellular division and growth. The descriptions of the indications, the various techniques, and the instrumentation conform to the requirements of a good textbook, and 143 satisfactory photographs demonstrate the final results.

In the part dealing with tissue and tissue-extract therapy, Filatov explains in detail the hypothesis which he elaborated, with some support from known biologic and botanical phenomena, to explain the rationale of this new form of therapy which is hailed in a tone of evangelism.

The numerous reports which appeared on this subject from the Ukraine Institute during the last five years had many of us wondering about the pharmacodynamics of what seemed to be advocated as a universal panacea. The fact that there were no reports on this subject from other Russian ophthalmological institutions, makes it probable that Filatov also met the normal scientific skepticism in Russia. This book is a detailed exposition of the motivation, the underlying hypothesis, the experimental data, the clinical studies, and the technique on the subject.

Preserved tissue and tissue-extract therapy is a nonspecific form of therapy, the therapeutic agent being designated as biogenic stimulators, or resistance substances, the existence of which is assumed, and the chemical nature of which is still in the process of investigation, the probability being that they are amines. They develop as a result of biochemical reconstruction in all living tissues and plants in response to an unfavorable environment, which harasses life but does not extinguish it entirely. They in turn stimulate biologic processes, and it is believed that such a phenomenon takes part in the process of evolution. Animal or plant tissues isolated from their organism, and subjected to an unfavorable, but not mortal, environment also undergo biochemical changes, resulting in the production of these substances. Tissues rich in these substances, introduced into another organism, become stimulants of the physiologic functions of the host.

In disease, pathogenic products inhibit the production of substances necessary for regenerative processes; and, on the other hand, the same pathologic process after reaching a certain intensity and duration initiates the development of biogenic stimulants; the crisis of acute infectious diseases is interpreted as the indication of a spurt in their appearance. The introduc-

tion into a sick organism of tissues rich in biogenic stimulants augments its cellular metabolism, and counteracts the inhibiting effect of pathogenic products on the formation of substances necessary for recovery. The unfavorable environment giving impetus to the formation of biogenic stimulators comprises variations in temperature and light, and various chemical agents. This in substance is the theory on which this form of therapy is based. Filatov believes that this type of therapy is in its inception, and that there are many problems yet to be cleared up.

How can maximum action of these substances be obtained? How can they be isolated? There are problems of sterility and stability; there is the possibility of specific stimulants. This, he says, is too big a task for a single investigator and he seeks to interest other workers. The techniques for the preparation of the various preserved homologous, heterogeneous, and plant tissues and extracts, and their therapeutic application are described in detail, in the hope that this information will lead to their wider use. Filatov foresees that the hypothesis may not stand the test of future investigations, and may be substituted by another theory based on a more factual foundation. Extensive clinical research may limit the sphere of usefulness of this form of therapy. But, whatever the explanation, he believes that the therapeutic effect of preserved tissue has been demonstrated and will remain incontrovertible.

The clinical material subjected to this type of therapy consists chiefly of hopeless cases, discharged as such from other ophthalmologic institutions. It is not difficult to understand that in such cases even very slight improvement may lead to an exaggerated enthusiasm. During the war the effectiveness of this therapy appears to have been confirmed in the various military hospitals, principally in Mid Asia,

where Filatov and his students worked. Regardless of the fate which the future holds for this form of therapy, the patience and the deep human sympathy motivating the sustained and prolonged efforts to restore to practically blind people a semblance of vision, adequate perhaps only to enable them to get about unaided, command our respect. The language barrier will make Filatov's book inaccessible to most ophthalmologists, and it is hoped that this review will at least define the pattern of his work.

Ray K. Daily.

RESEARCHES ON NORMAL AND DEFECTIVE COLOUR VISION.

By W. D. Wright, A.R.C.S., D.Sc., with a foreword by L. C. Martin, D.Sc., A.R.C.S., D.I.C., St. Louis, C. V. Mosby Co., 1947. Clothbound, 383 pages, 233 illustrations. Price, \$10.00.

This volume is the last word on experimentation and theory of color vision. It is the result of some 20 years of research. L. C. Martin, professor of Technical Optics in the Imperial College of Science and Technology, London, states, in the foreword, that the fundamental problems of color vision are still unsolved. The author writes: "This book should be regarded first and foremost as a record of experimental data, with theoretical discussion and speculation occupying a very secondary position." He goes on to express his personal belief that the three-response theory along lines proposed by Young and Helmholtz is probably correct. He does not, however, wish to ally himself too strongly with any theory as he believes that much work remains to be done. His opinion is that many exact experiments, the suggestions for which have already been made, should be performed as an aid toward establishing incontrovertible theory.

The first 40 pages are devoted to the

anatomy of the visual organ and the physiology of visual perception. Each succeeding chapter is introduced by a paragraph or two outlining the work contained in that chapter and in some cases descriptions of instruments that were used in the experimental work.

Most attention is devoted to the trichromatic system which is discussed exhaustively. If the mathematical details are passed over briefly by the average reader, much of practical interest to him will be found. Obviously the mathematics and other details are vital to the deeply interested student of color vision and to such a person the book is invaluable. It also will serve as a good reference book of the most recent researches in this field.

Lawrence T. Post

CORRESPONDENCE

Editor,

American Journal of Ophthalmology:

In the April, 1947, issue of the JOURNAL (page 491), Dr. S. Rodman Irvine reported on the January meeting of the Research Study Club of Los Angeles. In his report on my presentation of the subject of retinal detachment, he stated that I felt that about 10 percent of the detachments have a hole in the macula area that needs treating. This is a serious misunderstanding which, I feel, should be cleared up. I feel that probably one percent, or at most two percent, of detachments have a hole in the macula. I feel that many operations for a hole in the macula have been done when there was no hole present. I would appreciate it very much if this statement could be published to correct the impression created by Dr. Irvine's excellent résumé of the Los Angeles meeting.

(Signed) Dohrmann K. Pischel,
San Francisco, California.

ABSTRACT DEPARTMENT

EDITED BY DR. F. HERBERT HAESSLER

Abstracts are classified under the divisions listed below, which broadly correspond to those formerly used in the Ophthalmic Year Book. It must be remembered that any given paper may belong to several divisions of ophthalmology, although here it is mentioned only in one. Not all of the headings will necessarily be found in any one issue of the Journal.

CLASSIFICATION

- | | |
|--|--|
| 1. General methods of diagnosis | 10. Retina and vitreous |
| 2. Therapeutics and operations | 11. Optic nerve and toxic amblyopias |
| 3. Physiologic optics, refraction, and color vision | 12. Visual tracts and centers |
| 4. Ocular movements | 13. Eyeball and orbit |
| 5. Conjunctiva | 14. Eyelids and lacrimal apparatus |
| 6. Cornea and sclera | 15. Tumors |
| 7. Uveal tract, sympathetic disease, and aqueous humor | 16. Injuries |
| 8. Glaucoma and ocular tension | 17. Systemic diseases and parasites |
| 9. Crystalline lens | 18. Hygiene, sociology, education, and history |
| | 19. Anatomy, embryology, and comparative ophthalmology |

RETINA AND VITREOUS

Cristini, G. Retinal spongioblastoma. *Rassegna Ital. d'Ottal.*, July 1943-Dec. 1945, v. 12-14, pp. 450-467.

The author reviews the various phases of the development of our knowledge of the pathology of retinal tumors from the time of Virchow in 1869. The different classifications proposed by numerous investigators are presented. He describes a retinoblastoma observed in a 28-months-old child, which extended outside the globe, along the optic nerve and the vorticosae veins. Histologically there were two distinct areas, one portion showing spongioblasts which were highly anaplastic, and the other astroblastic. It would appear, therefore, that neoplasms may arise in the retina which are analogous to those which develop in the encephalon. (10 figures.)

Eugene M. Blake.

Cutler, N. L. Vitreous transplantation. *Trans. Amer. Acad. Ophth.*, 1947, March-April, pp. 253-259.

The vitreous contains about 99 per cent water yet has a viscosity 20 to 200 times higher than water. It is a solgel in an unstable state, subject to syneresis under various conditions.

The results of 13 vitreous transplants, of which eight were done for vitreous hemorrhage and five for retinal detachment, are summarized. Of the former four were considered successful and one partially successful; of the latter, one was successful. In eyes with hemorrhage, the vision improved from light perception to 20/50 and from 20/200 to 20/25. All the operated patients previously had normal light perception and tension.

Following sodium pentothal anesthesia and scleral exposure, a 2-mm. incision is made through the sclera with a Graefe knife. Mattress scleral sutures are then placed and 1.5 cc. of vitreous is withdrawn with a syringe and 18 gauge needle. The barrel is disconnected but the needle is left in place. A syringe barrel containing 2 cc. of clear vitreous from a freshly enucleated eye is attached to the original needle and

injected into the vitreous. The sutures are tied, atropine instilled, and a binocular dressing is applied.

Chas. A. Bahn.

Friedenwald, J. S. Disease processes versus disease picture in interpretation of retinal vascular lesions. *Arch. of Ophth.*, 1947, v. 37, April, pp. 403-427.

This article constitutes the Sanford R. Gifford Memorial Lecture of February 18, 1946. The four major, potentially independent, processes of vascular disease include senescence, atherosclerosis, the hypertensive arteriolosclerotic process and diabetic vascular disease. These processes are discussed in detail with special reference to the pathological changes involved. The comprehensiveness of this important article makes it unsuitable for condensation. John C. Long.

Fritz, M. H. The substitution of cerebrospinal fluid for vitreous clouded with opacities. *Amer. Jour. Ophth.*, 1947, v. 30, August, pp. 979-984. (12 references.)

Gördüren, Süreyya. A Grönblad-Strandberg syndrome. *Brit. Jour. Ophth.*, 1947, v. 31, April, pp. 228-232.

The author discusses the literature and presents an interesting case of Grönblad-Strandberg syndrome, with the two components of the disease, angioid streaks and pseudo-xanthoma elasticum, clearly demonstrated. Angioid streaks, which are due to the widespread degeneration of elastic tissue, were present in both eyes. A large, yellow, raised mass was present in the posterior pole of one eye. The skin of the neck and abdomen had a parchment-like appearance with raised yellow streaks. Microscopic examination of the skin in biopsy showed degenera-

tion of the elastic elements. (7 illustrations.)

Guyton, J. S., and Reese, A. B. The use of X-ray therapy for retinal diseases characterized by new-formed blood vessels. *Trans. Amer. Acad. Ophth.*, 1947, May-June, pp. 525-546.

In 14 patients 22 eyes were treated during 18 months with intensive X-ray therapy for vascular diseases of the posterior part of the eyeball. The doses ranged from 400 to 500 r three times weekly and were administered principally temporally. Eight patients had typical Eales disease, 4 had atypical Eales disease, and 2 had diabetic retinitis proliferans. Shrinking of the smaller vessels was observed two to three weeks after therapy and disappearance from ophthalmoscopic visibility occurred in 4 to 8 weeks. If the total dosage did not exceed 4,000 r the larger new-formed vessel showed partial shrinkage, but if more than 10,000 r the larger vessels disappeared. Regression of fibrous tissue was marked only with 10,000 r. In typical Eales disease hemorrhagic recurrence was observed but once. X-ray therapy was of no apparent value in diabetic retinoses. The marked friability of new-formed retinal vessels facilitates proliferative processes. X-ray therapy primarily affects new-formed blood vessels in the retina and vitreous. The total dosages used were 3,500-15,000 r per eye, the optimal dosage 6,000 r.

In the discussion, Alvaro reviewed the X-ray treatment of hemorrhagic retinal disease which dates back to 1919. Opinions concerning its efficiency vary widely. The effect of X-rays upon blood vessels is discussed in detail. In retinitis proliferans, the new formed blood vessels represent an effort to re-establish blood flow in an area of im-

paired circulation. Doses as small as 50 r repeated every five days have been advised. Larger doses are advised if blood vessels have formed at the disc and entered the vitreous. Hard rays are advisable in retinal therapy.

Blood in the vitreous is frequently absorbed more readily after therapy in doses of 300-1300 r. Hemorrhages in diabetic retinopathies are best treated with small doses, though the proliferative vascular process is not appreciably affected. Retinal thrombosis and occlusion of the central vessels with hemorrhage are not altered by X-ray therapy. (22 figures, 10 in color.)

Chas. A. Bahn.

Iglesias, F. G. Etiology and treatment of recurrent vitreous hemorrhages in the young. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1947, v. 7, Feb., pp. 139-162.

A comprehensive review of the literature is presented. Ray K. Daily.

Kinney, T. D., and Fitzgerald, P. J. Lindau-von Hippel disease with hemangioblastoma of the spinal cord and syringomyelia. *Arch. Path.*, 1947, v. 43, May, pp. 439-455.

The authors present two cases of Lindau-von Hippel disease.

Irwin E. Gaynon.

Klein, B. A. Angioid streaks. *Amer. Jour. Ophth.*, 1947, v. 30, August, pp. 955-968. (10 figures, 14 references.)

Matteucci, P. Contribution to the treatment of central retinal vein thrombosis. *Rassegna Ital. d'Ottal.*, July 1943-Dec. 1945, v. 12-14, pp. 394-404.

Three cases of retinal vein thrombosis are reported with satisfactory results from treatment with retrobulbar injections of alcohol. One cc. of 2-per-

cent novocain is first injected, and after an interval of five minutes one cc. of 70-percent alcohol is introduced. The treatment is repeated in a week if necessary. The good results are ascribed to a transitory hypotension of the globe accompanied by a dilation of orbital, retinal, and uveal vessels. A similar reaction is found in experimental animals. The treatment is recommended in painful glaucoma that is hemorrhagic, absolute, or secondary to iridocyclitis.

Eugene M. Blake.

Scuderi, Giuseppe. The effect of adrenalin, ephedrine and simpamina upon arterial retinal pressure. *Rassegna Ital. d'Ottal.*, 1947, v. 16, Jan.-Feb., pp. 3-40.

Adrenalin and ephedrine injected subcutaneously in doses of 1 mg. and 5 ctg. respectively, lower the retinal arterial pressure, especially the diastolic. This is probably due to a passive, compensatory hyperemia. Simpamina (betaphenylisopropalamina sulfate) on the contrary, in doses of 20 to 40 mg. produces a constant elevation of the pressure, whereas 10 mg. has only a negligible effect upon the diastolic pressure. The author suggests that the retinal arteries are capable of less contractility, and thus are less sensitive than other vascular regions of the body. (3 tables, 39 references.)

E. M. Blake.

Silfverskiöld, R. P. Retinal periphlebitis associated with paraplegia. *Arch. Neurol. and Psychiat.*, 1947, v. 57, March, pp. 351-357.

The author describes three cases of a remarkable syndrome. The patients, young men of about 30 years of age, first exhibited characteristic retinal periphlebitis with recurrent hemorrhages in the vitreous. After varying

intervals of time, only four to six weeks in two cases, the ocular disease was followed by subacute paraplegia, with considerable pleocytosis. During the follow-up period of one to two years the patients were observed to show improvement in varying degrees.

An investigation showed that a combination of retinal periphlebitis and neurologic disease is rare.

Theodore M. Shapira.

Stine, G. H. Detachment of the choroid and the retina. Anatomic and other considerations in the differential diagnosis. *Amer. Jour. Ophth.*, 1947, v. 30, July, pp. 897-906. (1 table, 3 figures, 22 references.)

Taylor, Charles. A Case of the Laurence-Moon-Biedl syndrome showing atypical retinitis pigmentosa associated with macular dystrophy. *Brit. Jour. Ophth.*, 1947, v. 31, April, pp. 211-215.

A case report of Laurence-Moon-Biedl syndrome is presented which shows the rarely-seen combination of atypical retinitis pigmentosa and macular dystrophy. The retina showed scattered pigment, and the macula was spotted with pigment. The vision was poor. The "bone corpuscle" pigmentation was not predominant. The author points out the interesting fact that analyses of reported families of this condition revealed a large number of miscarriages and early deaths, indicating severe disturbances in the genes.

O. H. Ellis.

Weinstein, P., and Forgács, J. Circulatory studies of the fundus of the eye. *Brit. Jour. Ophth.*, 1947, v. 31, April, pp. 238-242.

According to the authors, patients with spontaneous venous pulsation of the fundus blood vessels have a better

retinal circulation and show 50 percent less retinal complications than persons without pulsation. In patients with pulsation the pressure drop from the arterial to the venous circulation is greater; without pulsation the arterial pressure is established at a higher level signifying capillary obstruction. Spontaneous venous pulsation disappears with reduction of intraocular tension by massage of the globe.

O. H. Ellis.

11

OPTIC NERVE AND TOXIC AMBLYOPIAS

Casari, G. F. Alveolar meningioma of the optic nerve sheath. *Rassegna Ital. d'Ottal.*, 1947, v. 16, March-April, pp. 137-148.

The tumor described appeared in a 39-year-old man. The first symptom was epiphora, soon followed by progressive exophthalmos of the left eye. The interest in the tumor arises from its rarity and from its location. It had developed in the sheath of the nerve just posterior to the optic foramen. Usually the process starts in the intra-orbital portion of the nerve. The cytologic picture of the tumor is fully described. The author discusses the development of tumors of the sheath, the nerve, and those of the sheath and the nerve. (4 figures.) Engene M. Blake.

Lian, S. B. Camp amblyopia. *Ophthalmologica*, 1947, v. 113, Jan., pp. 38-44.

During the Japanese occupation of Java (1942-1945), the author saw many cases of an eye condition which he had never seen before and which the Dutch physicians assigned to the concentration camps had named "camp amblyopia." The condition occurred in

white males who had been put into concentration camps where improper and bad food prevailed. The patients' chief complaint was inability to read. Ophthalmologic examination revealed reduced central visual acuity, central scotomas, normal eye grounds (except for small striate retinal hemorrhages in a few patients) and no gross systemic abnormalities. Toward the end of the Japanese occupation when the food situation had become worse, the author saw the same condition among free (uninterned) civilians, first in the clinics for the indigent and later in his private practice. After a review of the literature pertaining to this and similar conditions (which had occurred in China, Japan and certain parts of Africa long before the last war), Lian reports five cases of camp amblyopia in patients who showed remarkable improvement after the addition of vitamin B₁ to their otherwise unchanged diet. Although favorable results were obtained with thiamin chloride alone, the author thinks that camp amblyopia is not simply a deficiency of Vitamin B₁. None of the patients with camp amblyopia showed any signs of beri-beri which still is the outstanding vitamin-B₁ deficiency disease. On the other hand, in true beri-beri, optic nerve involvement is rare. Also, it seems significant that camp amblyopia did not occur in concentration camps in Holland and Germany where the food situation was as bad as in the Dutch East Indies. Therefore the author suggests that camp amblyopia is not entirely due to a B₁ deficiency but rather to a complex deficiency in which lack of protein and minerals is an important factor. The problem of camp amblyopia is rather complicated, and there is much further work to be done.

Peter C. Kronfeld.

12

VISUAL TRACTS AND CENTERS

Kravitz, Daniel. Arachnoiditis. Arch. of Ophth., 1947, v. 37, Feb., pp. 199-210.

Arachnoiditis is an inflammation of the leptomeninges which may be localized or diffuse, even to the extent of involving the entire central nervous system. Infection, especially of the paranasal sinuses is the commonest cause. Syphilis, trauma, and otitis are other important causes. The symptoms may vary considerably depending on the location, extent and severity of the lesion. Headache is frequent. In the opticochiasmal form, sight is frequently jeopardized and the discs are rarely normal. There may be primary, secondary, or segmental atrophy of the nerve, or even extreme degrees of choked disc. At times arachnoiditis may simulate cerebral tumor so closely that the true pathologic process is not revealed until operation is performed. At times the optic nerve is severely damaged by sharing in the same inflammatory process that produced the arachnoiditis. The most satisfactory treatment of arachnoiditis is the surgical separation of arachnoidal adhesions.

Nine cases of arachnoiditis treated surgically are reported.

John C. Long.

Lyle, D. J. Diagnosis of visual losses with normal fundus. Ohio St. M. J., 1947, v. 43, June, pp. 620-621.

Advanced arteriosclerosis and encephalopathies may produce visual loss without changing the normal appearance of the fundus. Affections of the retrobulbar optic nerves, chiasm, and optic tracts frequently do not produce changes in the fundus at first. The diagnosis is made by visual field studies, the reaction of the pupils, the

extraocular muscles, the trigeminal and facial nerves and other neurologic studies. Roentgenologic and other diagnostic aids should be used.

Vascular lesions most frequently are the cause of disturbance in the optic radiations. Tumors may cause visual hallucinations before they produce papilledema especially if present on the dominant side. The visual field defects from lesions in the radiations usually show sharp and congruous edges with sparing of the macular fibers.

The calcarine branch of the posterior cerebral artery is most frequently involved in lesions of the visual cortex. Vascular lesions frequently produce a large defect immediately, whereas lesions caused by expanding tumors become larger late and cause sector and indentation defects in the visual field. Visual illusions result from irritation to the psychic visual cortex chiefly from drugs, poisons, and toxins. Destruction of the para- or peri-striate areas cause a loss of visual perception, recognition, and revisualization.

H. C. Weinberg.

Monnier, M., and Jeanneret, R. L. Objective recording of the conduction process in the visual pathway by combined electroretinography and electroencephalography. *Ophthalmologica*, 1947, v. 113, Jan., pp. 1-11.

An interesting neurophysiologic study from the department of physiology of the University of Zurich is presented. Under conditions of complete sensory and mental rest, the electroencephalogram shows oscillations of a certain frequency and intensity which have been designated as alpha rhythm. Sensory stimulation characteristically inhibits or arrests the alpha rhythm (réaction d'arrêt, arrest reaction). This phenomenon of inhibition of a cortical

activity by a sensory stimulus promises to permit closer study of the functional status of the visual pathway. Bertrand, Delay and Guillain in their monograph on electroencephalography (Masson & Cie, Paris, 1939) mention a patient with right-sided homonymous hemianopsia and aphasia whose alpha rhythm remained undisturbed by visual stimuli if the lead (for the electroencephalogram) was taken from the left occipital region. If the lead was taken from the right occipital region, typical alpha rhythm was obtained which was typically inhibited by visual stimuli. The authors (Bertrand, Delay and Guillain) attribute the ineffectiveness of visual stimuli upon the alpha rhythm emitted by the left occipital lobe to the obviously existing interruption of the left suprageniculate pathway.

The authors of the paper under review have studied the latent period of the arrest reaction (the so-called blocking time), in the hope that it would prove to be a finer, "more differentiated" criterion of the functional status of the visual pathway than the mere fact of presence or absence of the arrest reaction. The blocking time is determined in human subjects by combining electroencephalography with electroretinography. The examinee is seated before a perimeter on the arc of which the apparatus that provides the visual stimulus is mounted. The latter consists of a standardized light source, a projection system and colored filters. The leads for the electroretinogram are taken from the conjunctival cul-de-sac and from the temporal region, those for the electroencephalogram from the occipital region and from the lobule of the ear. Cathode oscillographs are used to record the variation in potential. After the alpha rhythm has been obtained and recorded for a few seconds,

a visual stimulus is applied. It causes (1) a subjective sensation, (2) the various phases of the electroretinogram and (3) inhibition of the alpha rhythm of the electroencephalogram. The blocking time, that is the time from the inception of the light stimulus to the very beginning of the inhibition of the alpha rhythm, has been found to be 0.169 second (for a normal subject under conditions of foveal stimulation). The simultaneously taken electroretinogram permits determination of the retinal portion of the blocking time, that is the time from the onset of the visual stimulation to the moment the impulses are discharged into the optic nerve. This retinal portion or retinal time has been measured to be 0.045 second (under the conditions stated above). By deducting this retinal portion from the total blocking time the postretinal or central time is obtained (0.124 second) which corresponds to the conduction time of the impulses within the visual pathway. In a patient with tabetic optic atrophy the postretinal time was found to be considerably longer and more variable than in the normal. Combination of electroencephalography and electroretinography promises to be a valuable method for the study of normal and abnormal conduction in the visual pathway.

Peter C. Kronfeld.

Verdaguer, J., and Olivares, M. L. Parinaud's mesencephalic paralysis. *Arch. Chilenos de Oft.*, 1946, v. 2, July-Oct., pp. 226-234.

The patient, a man aged 33 years, came complaining of almost continuous occipital headache, dizziness, and uncertain gait. Examination showed incomplete paralysis of associate movements of elevation, incomplete paralysis of convergence, and Argyll Robert-

son pupil. Ventriculography had not yet been done, but the diagnostic impression was of a tumor of the quadrigeminal region. (References.)

EYEBALL AND ORBIT

Delsors, José, and Matheu Climent, J. Fracture of the optic canal. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1946, v. 6, June, pp. 536-543.

The authors report a case of skull fracture with involvement of the optic canal. A series of good X-ray pictures is presented to show the fracture that involves the optic canal. (7 illustrations.)

J. Wesley McKinney.

English, P. B. Calcification occurring in the eye. *M. J. Australia*, 1947, May 3, pp. 549-551.

Calcification may take place in the tarsal plate in chronic trachoma and in the conjunctiva in vernal catarrh and erysipelas. In the cornea it may be primary or may be secondary to hyaline degeneration. It is common at the optic disc and ora serrata and it also occurs in the sclera between the fibrils. The author reports a case in which the sclera, lens and vitreous were the seat of calcification after a postinflammatory fibrosis. (References.)

Irwin E. Gaynon.

Givner, I., Bruger, M., and Lowenstein, O., Exophthalmos and associated ocular disturbances in hyperthyroidism. *Arch. of Ophth.*, 1947, v. 37, Feb., pp. 211-219.

In 21 of 22 patients with hyperthyroidism, pupillographic examination revealed a re-dilation block. This is believed to be hypothalamic in origin and lends the first tangible evidence to the confirmation of Marine's hypothesis

that exophthalmos is due to a stimulation of the hypothalamic centers which in turn stimulates the pituitary to produce the thyrotropic hormone, which in turn stimulates the thyroid gland, and, independently, the sympathetic centers in the midbrain, causing exophthalmos.

The administration of neostigmin bromide, a preparation of vitamin E and pyridoxine failed to reduce exophthalmos. Ergotamine tartrate temporarily and substantially reduced exophthalmos. The administration of iodine orally, and pregnancy may occasionally result in regression of exophthalmos.

If vision is impaired because of involvement of the optic nerve in patients with thyrotropic exophthalmos, complete uncapping of the optic foramen should be included in the Naffziger decompression. John C. Long.

Kennedy, R. J. Ocular hemorrhages. *Cleveland Clin. Quart.*, 1947, v. 17, July, pp. 176-180.

Subconjunctival hemorrhage may result from trauma, compression of the chest, scurvy, or purpura. Vitreous hemorrhage occurs from trauma, arteriosclerosis or retinal inflammation. Retinitis proliferans is a serious sequel of vitreous hemorrhage. Occlusion of the central retinal artery causes a sudden loss of sight with the "cherry-red spot" at the macula. Hemorrhages may be small at the disc. Occlusion of the central retinal vein may be complete with a gradual loss of vision. The veins are dilated and the retina is covered with superficial and deep hemorrhages.

Hemorrhages in the uveal tract occur in arteriosclerosis, in iritis, and in the blood diseases. Choroidal hemorrhages produce permanent visual defects.

The vascular retinopathies are characterized by hemorrhage and exudate

in addition to sclerosis, hypertension and toxemia. The striate and flame shaped hemorrhages are superficial in the retina whereas the round and irregular ones are in the deep layers of the retina. (2 figures.)

H. C. Weinberg.

Magitot, A. The implantation of dead tissues in ophthalmology. *Ann. d'Ocul.*, 1947, v. 180, March, pp. 146-149.

Dead tissues used as implants in the orbit have one advantage over live tissues; they are absorbed less rapidly. Foreign substances, if similar embryologically, are usually well tolerated by the host. If cartilage is used the perichondrium should be removed. Cartilage preserved in formalin and alcohol, makes an excellent implant because it is easily vascularized and encysted. The author prefers the head of the femur of a dog that weighs about 15 Kg. It may be preserved in alcohol or formalin or sterilized in the autoclave and preserved in a sealed glass tube. Expulsion of tissue implants is less frequent than of inert substances such as metals or plastics. Implants should be covered by the ocular muscles, Tenon's capsule, and the conjunctiva. There is a moderate edema for four or five days and the implant is firmly fixed at the end of a week. The unsightly fold in the upper lid which is not infrequent after enucleation may be remedied by a cartilage implant.

The nerves in tissue implants do not survive. Corneal transplants from horses usually remain transparent in rabbits. Transplanted glandular epithelial implants such as the ductless glands frequently remain viable and in some cases functional. In successful corneal transplants keratoblasts from the host progressively replace those in the implant. Chas. A. Bahn.

Somerville-Large, L. B. **Panophthalmitis in a premature infant treated by streptomycin.** *Brit. Jour. Ophth.*, 1947, v. 31, June, pp. 362-366.

A case of panophthalmitis in an 11-day-old, premature infant is reported. Pure-cultures of bacillus proteus were obtained from the umbilical cord and the anterior chamber. The infection proved resistant to combined sulfadiazine and penicillin. It responded to streptomycin although not in time to prevent perforation and evisceration. Negative cultures were obtained from the excised uveal tissue which demonstrated the intraocular permeation of the streptomycin. O. H. Ellis.

EYELIDS AND LACRIMAL APPARATUS

Alvarez y Alvarez, Abundio. **Plastic surgery of the lids.** *Arch. de la Soc. Oft. Hisp.-Amer.*, 1946, v. 6, Nov., pp. 1163-1173.

Imre's technique of plastic surgery of the lids is described. The author has obtained good results by using this method with some variation of his own, in which he uses sliding triangular flaps with curved borders and horizontal bases. (4 illustrations.)

J. Wesley McKinney.

Baclesse, F., and Ennuyer, A. **Indications for contact radiotherapy in the treatment of oculopalpebral tumors.** *Arch. d'Ophth.*, 1947, v. 7, no. 1, pp. 5-17.

The authors have treated more than 200 tumors of the external eye and lids in the past four years, of which 150 were epitheliomas of the lids, 2 were epitheliomas of the cornea, 2 were conjunctival lymphomas, and 25 were palpebral angiomas. The technic of so-called "contact radiotherapy" consists in the use of low voltage (50-60 K V),

short focus (2-5 cm.), and minimal filtration. Its purpose is to give the first few millimeters of the lesion the maximum dosage while sparing the subjacent tissues. The authors consider it unnecessary to shield the globe when employing this technic and they have encountered no late unfavorable effects. They feel that their results have been exceptionally good.

Phillips Thygeson.

Barraquer Burch, Manuel. **A contribution to dacryocystorhinostomy.** *Arch. de la Soc. Oft. Hisp.-Amer.*, 1946, v. 6, Nov., pp. 1150-1160.

With little change in the customary technique the author successfully performed 29 dacryocystorhinostomies. In suturing the anterior flap he only put two interrupted silk sutures through the skin, nasal mucosa, lacrimal sac and back through the skin again. The stitches are tightened over a small piece of gauze which can be very easily removed. (10 illustrations.)

J. Wesley McKinney.

Bock, R. H. **A simple modification of operations for entropion of the eyelids.** *Arch. of Ophth.*, 1947, v. 37, May, pp. 650-651.

The method described makes use of the principle of the Hotz operation, namely, to fix the margin of the lid to the upper border of the tarsus by sutures. This, however, is done without cutting the skin, but only by passing three or four double-armed sutures from the conjunctival side through the upper border of the tarsus, then along the anterior surface of the tarsus downward and finally emerging through the skin 1 to 2 mm. above the row of eyelashes. The other end of the silk suture is passed in the same way about 2 mm. away from the first one, and the two

are tied on the skin side over a glass pearl on a small gauze roll after-exerting the necessary pull to produce the desired correction. (1 figure.)

Carreras Durán, B. **A contribution to dacryocystorhinostomy.** Arch. de la Soc. Oft. Hisp.-Amer., 1946, v. 6, Nov., pp. 1132-1137.

To prevent injury to the nasal mucosa while trephining the bone in dacryocystorhinostomy, the author advises an injection (1 or 1.5 cc.) of 3-percent novocaine in oil, placed under the nasal mucosa at the site of the perforation. This will separate the membrane from the bone and prevent injury of the mucosa. He describes a simple syringe to be used for the injection. (2 illustrations.) J. Wesley McKinney.

Carrearas Durán, B. **Rare disturbances after Toti's operation.** Arch. de la Soc. Oft. Hisp.-Amer., 1946, v. 6, June, pp. 553-557.

A rare complication following a dacryocystorhinostomy is reported. The patient noticed a temporary change in her voice that lasted a few days two months after the operation.

J. Wesley McKinney.

Casero, L. **Inverse Bell's phenomenon.** Arch. de la Soc. Oft. Hisp.-Amer., 1946, v. 6, June, pp. 588-592.

In the normal Bell's phenomenon there is elevation and slight outward deviation of the eyeball when the lids are closed and in the inverse phenomenon the deviation of the eyeball is down and inward. A boy, 16 years old, with an inverse Bell's phenomenon is reported. The patient had suffered a traumatic wound on his right upper lid six years before examination. After this

was healed there was an ectropion of the lid with conjunctival hypertrophy and an inverse Bell's phenomenon of the right eye. The abnormality is an acquired abnormality of oculomotor synergy. J. Wesley McKinney.

Chavarria López, F. A. **Large polyp of the right lacrimal sac with spontaneous healing.** Arch. de la Soc. Oft. Hisp.-Amer., 1946, v. 6, Nov., pp. 1127-1131.

The polyp developed in a patient who formerly had bilateral dacryocystitis, and at the time that he presented himself for examination had an acute attack of dacryocystitis of the right side. The polyp separated itself from the sac after spontaneous healing of the process.

J. Wesley McKinney.

Cornalba, Gaetano. **A case of cylindroma of the lacrymal gland.** Rassegna Ital. d'Ottal., 1947, v. 16, Jan.-Feb., pp. 41-49.

A 29-year-old man developed gradual exophthalmos and displacement of the left globe. The histologic picture showed the morphologic characteristics of a cylindroma of the orbit, originating in the lacrymal gland. The tumor consisted of mixed epithelial and endothelial cells with participation of fibroblastic tissue. (7 figures, 21 references.)

Fox, S. A. **Lipiodol studies of chronic dacryocystitis.** Amer. Jour. Ophth., 1947, v. 30, July, pp. 878-884. (9 figures, 10 references.)

Landau, J. **A case of congenital vertical shortness of the lids combined with tetrastichiasis.** Brit. Jour. Ophth., 1947, v. 31, April, pp. 219-222.

The author reviews the literature, and presents an unusual case of congenital vertical shortness of the lids. The patient also had tetrastichiasis, combined with a partial eversion of the cutaneous part of the upper lid margin. It appeared that the hair follicles of the supernumerary cilia had taken the place of the Meibomian glands, and occupied their ducts. No inflammation of the eyes had occurred. O. H. Ellis.

Leriche, Rene. Surgical treatment of Sjögren's syndrome; the result, after 28 months, of bilateral section of the vertebral nerve. *La Press Medicale*, 1947, no. 7, Feb. 1, pp. 77-78.

Leriche reports the case of a woman 50 years of age who consulted him because of dry mouth and dry eyes of 12 years duration. Her general health was good except for menopause which had taken place during the course of her disease. The eyes showed complete absence of tears as measured with filter paper. Repeated sympathetic blocks with procaine each time produced a hyperemia of the facial region with lessening of the dryness of the mucous membrane. The roots of the vertical nerve on the right side were cut and a substellar segment of the cervical sympathetic chain which included the intermediate ganglion, was excised. There was immediate improvement subjectively and objectively. Five days later section of the roots of the vertebral nerve on the left side resulted in definite return of tears and subjectively the patient was much improved. The postoperative course was interesting in that the moisture in the mouth was maintained and the patient was able to shed tears for the first time in many years. The patient died 28 months later after a hemorrhagic purpura. Her hus-

band stated that at the time of his wife's death she had still not obtained a true salivation but that her mouth was always sufficiently moist.

The author considers that surgical intervention is justifiable in a condition in which ordinary therapy is useless. He believes that the atrophy of the salivary and lacrimal glands may result in part from vascular failure and that surgical therapy leads to an active hypermia of these glands. The latter would be expected to increase their function.

In discussing surgical technique he considers it unjustifiable to remove the stellate ganglion because of the subsequent interference with the function of the heart-regulating mechanism and of the vasoconstrictors of the upper arms. The stellar ablation of the second and third dorsal ganglia would have the advantage of not producing Horner's syndrome. He states that his procedure of sectioning the vertebral nerve roots on the two sides is not the ideal operation since it leads to circulatory changes that are more cerebral than facial. It might be advisable to attack the middle part of the cervical chain, from the middle ganglion to the lower pole of the superior ganglion.

In discussing the pathogenesis of Sjögren's syndrome, Leriche considers the possibility that the disease may originate in a vasomotor disturbance that leads to elective atrophy of the glands. Phillips Thygeson.

Marin Amat, M. Importance of the deep suture in dacryocystorhinostomy. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1946, v. 6, Nov., pp. 1138-1149.

The author believes that success in dacryocystorhinostomy depends on the deep suture placed in the lacrimal sac

and nasal mucosa. He describes his own technique.

Sherman, A. E. Reconstruction of the eyelid. *Trans. Amer. Acad. Ophth.*, 1947, May-June, pp. 514-524.

Three to four hundred patients with severe lid injuries were observed in nine Army General Hospitals during two years. Generally speaking, eyelid tissues should be replaced by eyelid tissues. The Wheeler technique which employs a full thickness graft carefully sutured in a previously prepared bed with excision of scar tissues is preferred. A good pressure dressing is considered important and should not be changed for five or six days. For small full-thickness losses and for vertical scars Wheeler's "halving" technique is advised. In younger patients the Hughes method of lid reconstruction is considered superior to Wheeler's sliding flap correction. If possible, avoidance of pedicle flaps from the forehead and cheek is advised. The Hughes method of total lower lid reconstruction is preferred if the tarsal part of the lid is missing. In extensive losses, the skin and subcutaneous tissue are elevated and with the conjunctiva are joined to the upper tarsus at a second operation. Bone grafts from the crest of the ilium

may be used if necessary. Eyelash grafts are best taken from the middle portion of the nasal end of the eyebrow. Total reconstruction of the upper lid is not as satisfactory as that of the lower. Three illustrative cases are presented showing the use of full-thickness grafts. Two cases illustrate the "halving" operation; two cases, the total reconstruction of the tarsal portion of the lids by the Hughes method; and three cases, the Hughes method of lid reconstruction combined with other procedures. INJURIES

Casnovas, José. Double perforation of the eyeball in accident work. *Arch. de la Soc. Oft. Hisp-Amer.*, 1946, v. 6, June, pp. 523-535.

Of 73,750 patients with ocular traumatism, 98 had a perforated wound with an intraocular foreign body. In 13 cases of double perforation of the

eye the foreign body was found to be within the orbit. The last 13 cases are reported in detail. (8 illustrations.)

J. Wesley McKinney.

Desvignes, P., and Boudon, C. **Statistical study of 418 penetrating injuries of the globe treated at the ophthalmological clinic of the Hotel-Dieu, from 1940 to 1945.** *Arch. d'Opht.*, 1947, v. 7, no. 1, pp. 28-50.

The authors note the increase in the number of penetrating wounds as compared to the 394 cases reported by Dollfus and Halbron for the same hospital for the years 1925 to 1933. They explain this increase in part as a result of war injuries and in part as a result of the closing of other hospitals during the war years. Young adults were most commonly involved and of the 399 unilateral cases 322 were in males. There were 19 bilateral injuries, all but one of which were war injuries. Cause of the injury was known in 337 cases and of these 87 were industrial accidents with penetrating metallic foreign bodies; in 26 cases the penetrating agent was wooden. There were 72 infants in the series.

Prognosis varied according to the nature of the traumatism and the site of the wound and the authors give tables illustrating the end results of the various injuries. The percentage of retained globes with useful vision varied from 2.4 percent in the case of mutilating injuries to as high as 55.2 percent in the case of injuries by non-retained metallic agents. The extent of the injury had more prognostic significance than the site. There were no instances of sympathetic ophthalmia observed in spite of the fact that in 78 cases there was persistent uveal tract inflammation.

The authors conclude that the sulfonamides did not prove to be of striking value in preventing infection and that the prognosis of perforating injuries of the globe has not improved materially over the past 40 years in spite of advances in chemotherapy and improvement in surgical technic.

Phillips Thygeson.

Ershkovich, I. G. **Tissue therapy of sequelae of ocular war injuries.** *Oftal. Jour. (Odessa)*, 1946, pt. 3, pp. 7-17.

This is an analysis of 250 cases of late sequelae of ocular war injuries treated at the Ukraine Eye Institute for long periods of time, in an effort to exhaust all possible therapeutic procedures for restoration of even a small fraction of visual acuity. Of 64 eyes of 58 patients with traumatic iridocyclitis, 38 had no form vision before the beginning of therapy, 25 had vision from counting fingers to 0.1, and only one eye had a visual acuity above 0.1. Of the 63 patients with vision below 0.1, 29 recovered a visual acuity of 0.1 to 1. Of 21 eyes with imperfect light projection 4 remained unimproved; in 2 eyes vision improved to normal light projection, in 3 to counting of fingers, and in the others to a slight but measurable visual acuity. It is significant that four apparently hopeless eyes in the subatrophic stage showed some improvement.

Twenty patients had profound damage to the vitreous, 14 as a result of a perforating injury, and six after contusion. Eleven eyes had an extensive exudate in the vitreous, which in six encapsulated an intraocular foreign body. Five had a retinal detachment. There was some improvement in 18 of them. The period of observation ranged from six weeks to four years.

Tissue therapy was strikingly effective as a postoperative measure in 26 out of 27 cases of posttraumatic sequelae. Of 67 patients with subatrophic eyes which would usually be enucleated, 32 were freed of invalidism by alternating courses of tissue therapy and surgical procedures.

Kashuk, M. E. Therapeutic use of autoclaved preserved tissue in the treatment of sequelae of military ocular injuries. *Oftal. Jour. (Odessa)*, 1946, pt. 3, pp. 17-20.

This is a report of a clinical investigation on 60 cases of traumatic ocular lesions, treated with implantation of sterilized preserved skin into a subcutaneous pocket behind the ear; and with implantation of sterilized preserved placenta into the subconjunctival sac. This therapeutic pattern had a definitely favorable effect on eyes with traumatic keratitis, traumatic purulent corneal ulcers, traumatic iridocyclitis, resistant to other forms of therapy, traumatic uveitis with vitreous opacities, and traumatic chorioretinitis. In nine out of 12 cases of traumatic optic atrophy visual acuity and the fields improved.

Ray K. Daily.

Khoroshina, A. G. Treatment of sequelae of ocular war injuries with preserved tissue. *Oftal. Jour. (Odessa)*, 1946, pt. 3, pp. 21-25.

A detailed analysis is reported of 15 patients treated with tissue therapy. The eyes were injured by mine or bomb explosions. Two eyes were damaged by contusions, and 14 eyes had perforating injuries. Most of these patients had been discharged from other hospitals after all other procedures proved futile. Objective improvement

and improved visual acuity was obtained in 12 eyes. In chronic iridocyclitis in subatrophic eyes the photophobia and irritative symptoms disappeared. Corneal leucoma became somewhat less dense, and in one eye a semitransparent transplant became transparent. Vitreous opacities were absorbed, and in optic atrophy the narrow arteries on the disk dilated.

Ray K. Daily.

Levkoieva, E. T. The regeneration of wounds of external membrane of the eye in the light of new pathologico-anatomical results. *Brit. Jour. Ophth.*, 1947, v. 31, June, pp. 336-361.

The author has studied sections from 6,000 eyes enucleated over a period of many years.

A clinical diagnosis of endophthalmitis is frequently disproved microscopically. Repeated hemorrhages occurring late are proof of constant irritation resulting from non-closed or badly closed wounds. The healing process and the fate of the perforated eye depends chiefly on the primary surgical treatment.

The author highly recommends direct apposition of wounds, and shows many photomicrographs of poorly approximated wounds when only the conjunctival flap of Kuhnt was used. Conjunctivoplasty closes the superficial layers but the deep edges are not brought into apposition. This encourages the excessive production of fibroblasts which results in a contracted scar, flattening of the wound area and an irritation of the eye, which is often difficult to differentiate clinically from sympathetic ophthalmia. In one clinic, proper suturing of all wounds of the cornea and sclera reduced the frequency of enucleations by 8.9 percent. (14 photomicrographs.) O. H. Ellis.

Paufique, L. Head of the femur implants after enucleation. *Ann. d'Ocul.*, 1947, v. 180, March, pp. 129-139.

Inert organic substances which have been used as implants are discussed in detail. The head of the femur of infants that died at the age of three to four months is considered the most desirable implant in Tenon's capsule. After removal, it is immediately placed in 20 percent formalin for eight hours and then in water for four hours. It is then placed successively in 40, 60, and 80 percent solutions of alcohol and at the end of eight hours in 95 percent alcohol. One-half hour before use it is put in normal salt solution. The proximal or spherical surface is forward and the cut end backward. Two catgut sutures are inserted in the anterior surface, one above and the other below the mid-line. The implant is placed in the muscle cone and the muscles sutured over it vertically and horizontally. The implant sutures are tied over the superior and inferior recti tendons. Tenon's capsule and the conjunctiva are sutured over the implant and muscles. The above technique may also be used to improve the appearance of prostheses when simple enucleation had been done. Through a linear undermining incision in the lower conjunctiva the implant is inserted and sutured in position. (24 references.)

Chas. A. Bahn.

Scripchenko, C. P. Tissue therapy of war invalids. *Oftal. Jour. (Odessa)*, 1946, pt. 3, pp. 25-29.

The tabulated data of the visual acuity of war-blind persons at the end of the treatment, which consisted of injections of extracts of leaves of aloes preserved in darkness, show definite, if minute improvement. Most responsive to this form of therapy are injuries of

the retina and choroid, and the treatment is least effective in methyl alcohol poisoning. Ray K. Daily.

Somerset, E. J. Foreign body localization: the ring method. *Indian M. Gaz.*, 1947, v. 82, Feb., pp. 50-53.

An antero-posterior and a lateral X-ray film are taken on which the shadow of the ring will appear as a perfect circle and a line, respectively, if the films are properly placed in relation to the eye. Measurements are taken and transferred to a schematic drawing of the eye. Whatever the magnification of the X ray, the diameter of the ring is known to be 12 mm., and all other measurements can be adjusted by simple calculation. Irwin E. Gaynon.

SYSTEMIC DISEASES AND PARASITES

Agundis, Teódulo. Marfan's syndrome. *Anales de la Soc. Mexicana de Oft.*, 1947, v. 21, April-June, pp. 113-123.

Two cases encountered personally are recorded by the author. The first was in a young woman who was sent to the ophthalmic service of the City Hospital of San Luis Potosí, with absolute glaucoma of the right eye, the crystalline lens of which was opaque and dislocated up and inward. The left eye had normal tension, but showed a luxation of the lens similar to that of the right eye. There was notable lengthening of the extremities with arachnodactyly. The second patient was a man of 28 years, with lifelong poor vision. The crystalline lenses were displaced upward and outward. The right eye counted fingers at 70 cm., the left at 40 cm. The ophthalmoscopic description of the disc suggests very high astigmatism. The limbs were

notably longer than normal, there was arachnodactyly, and the nails of some fingers were atrophic and corrugated. X-ray examination of the cranium, the hands, and the thorax yielded signs of acromegaly, and also of aortitis and cardiac hypertrophy. (References.)

W. H. Crisp.

Castresana y Guinea, Angel. Ocular myiasis. Arch. de la Soc. Oft. Hisp.-Amer., 1947, v. 7, Feb., pp. 163-172.

A case of external ophthalmomyiasis, which is rare in Spain, occurred in a six-year-old child, in whom the larvae of *Oestrus avis* were deposited in the conjunctival sac, while she was at play. A rapid inflammatory reaction of the conjunctiva and cornea ensued, and on examination numerous rapidly motile parasites were found and removed. Two small hemorrhages in the bulbar conjunctiva resulted either from direct trauma by the hooks of the parasite, or from a conjunctival necrosis produced by ferments of the parasite. The literature is reviewed, and the importance of early diagnosis is emphasized. Treatment consists in prompt extraction of the parasites, and the use of mercurial ointments. (2 illustrations.)

Ray K. Daily.

Franceschetti, A., and Bourquin, J. Rubella during pregnancy and congenital malformation of the infant. Ann. d'Ocul., 1946, v. 179, Dec., pp. 623-627.

Practically every expectant mother who has rubella during the first part of pregnancy must expect a malformed child. Among 479 infants of mothers that had measles during the first part of pregnancy, that have been reported there were included 274 cases of cataract and other ocular malformations, 52 of microphthalmus, 215 of deafness,

and 181 of cardiac malformation. Two types of cataract were observed; one central with transparent periphery and the other total, usually flat and membranous. Fundus pigment changes, especially in the macula, were frequently present. Five additional cases are described.

In pregnant women who have been exposed, immunizing serum should be used. The advisability of therapeutic abortion must be seriously considered.

Chas. A. Bahn.

Givner, I., Bruger, M., and Lowenstein, O. Exophthalmos and associated ocular disturbances in hyperthyroidism. Arch. of Ophth., 1947, v. 37, Feb., pp. 211-219. (See Section 13, Eyeball and orbit.)

Grammatico, A. D. Ophthalmologic contribution to the diagnosis and treatment of headache. Arch. de Oft. de Buenos Aires, 1946, v. 21, Aug., p. 219.

A chronic headache of many years resulted from vascular instability. The instillation of ergotropylin in the eyes together with thyroid therapy internally and adequate diet brought about a complete cessation of the headaches and a definite enlargement of the visual fields. (Tables, visual field charts, bibliography.)

Plinio Montalván.

Graue, Enrique. A year in the Xoquiapan leprosarium. Anales de la Soc. Mexicana de Oft., 1947, v. 21, Jan.-March, pp. 23-30.

As titular ophthalmologist of the "Dr. Pedro López" leprosarium at Xoquiapan, about 22 miles from the City of Mexico, the author has studied the lesions of the disease in various parts of the eye. The usual population of this settlement varies between four and five hundred patients, concen-

trated by the Mexican Department of Public Welfare from various leprogenous zones of the Republic. The cornea is the tissue most frequently affected. The sclera, episclera, and iris follow and are almost alike in frequency of involvement. Some authors even believe that the eye is the usual portal of entry of the disease. W. H. Crisp.

Leriche, Rene. Surgical treatment of Sjögrens syndrome; the result, after 28 months, of bilateral section of the vertebral nerve. *La Presse Medicale*. 1947, no. 7, Feb. 1, pp. 77-78. (See Section 14, Eyelids and lacrimal apparatus.)

Paschkis, K. E., and Cantarow, A. Hyperophthalmopathic syndrome in thyroid disease. *J. Clin. Endocrin.*, 1947, v. 7, Feb., pp. 102-114.

The occurrence of proptosis, paresis of external ocular muscles, swelling of the lids, edema of the conjunctiva, and retrobulbar pain in patients with thyroid disease is discussed as the hyperophthalmopathic syndrome. The five case reports demonstrate that the pathologic physiology is not completely understood. Thyroidectomy should be avoided in potential severe ophthalmopathy. Severe ophthalmopathy, far out of proportion to the thyroid toxic manifestations, is a clear contraindication to thyroidectomy.

The effect of iodine should be studied and medication continued to produce the lowest possible basal metabolic rate. Where there is the slightest doubt operation is inadvisable.

The emergency treatment of ophthalmopathy consists of protection of the eyes by local measures followed by decompressing operations. Medical treatment is directed to suppression of excessive secretion of the anterior lobe

of the pituitary gland. Large doses of estrogenic hormones suppress pituitary function and the secretion of the thyrotropic hormone. Thyroid medication primarily suppresses the thyrotropic hormone. X-ray therapy of the pituitary gland attempts direct suppression of the over-active gland. (3 Figures.)

Pedico, O. Orbital cysticercus. *Rassegna Ital. d'Ottal.*, 1947, v. 16, March-April, pp. 149-165.

Four stages in the development of the cysticercus which was present in the left orbit of a soldier, are described in detail. First there was slight discomfort and commencing impairment of ocular motility, then exophthalmos with marked chemosis of the conjunctiva, resulting from venous obstruction. In the third stage the tumor was palpable behind and above the globe. A fourth stage has been known, in which involvement of the accessory sinuses, cranial cavity and nasal fossae occur.

Aspiration of the mass gave a limpid fluid, containing hooklets, cells and a di-basic phosphate of calcium.

Eugene M. Blake.

Rosso, Silvio. The effect of estrogens upon the retinal arterial pressure. *Rassegna Ital. d'Ottal.*, 1947, v. 16, Jan.-Feb., pp. 3-16.

Rosso studied the retinal arterial pressure in patients with primary amenorrhea, follicular hypersecretion, dysmenorrhea, and normal menopause. After the patient was treated with various natural and synthetic estrogens further pressure readings were made. The estrogens have no effect upon people in hormonal equilibrium or where there is an estrogenic saturation. In primary amenorrhea there ex-

ists a marked sensitivity to the estrogen, which induces a retinal hypotension which lasts from a few hours to exhaustion of the supply of the hormone. (7 tables, 30 references.)

E. M. Blake.

Schmidtke, R. L. **Hypovitaminosis A in ophthalmology.** *Arch. of Ophth.*, 1947, v. 37, May, pp. 653-667.

The author has reviewed the literature of various experiments involving the use of vitamin A in the treatment of ocular diseases. He draws the following conclusions:

1. Hypovitaminosis A may exist in persons who presumably are receiving an adequate diet.

2. Even in the absence of demonstrable ocular lesions, poor dark adaptation is not presumptive evidence of vitamin A deficiency.

3. Fasting vitamin A levels of the blood are of value as a diagnostic aid in establishing the existence of a deficiency.

4. More reports on early ocular changes in vitamin A deficiency need to be made before biomicroscopic examination can be a real diagnostic aid.

5. The corneal and conjunctival lesions in vitamin A deficiency are probably neurotropic and result from degenerative changes in the trigeminal nerve.

6. Keratoconjunctivitis sicca is probably one of the many ways in which vitamin A deficiency manifests itself.

7. Some of the heretofore unexplainable ocular congenital anomalies are undoubtedly due to a vitamin A deficiency in the mother at some critical time during the period of gestation.

8. Vitamin A deficiency may be caused by (a) reduced consumption; (b) defective absorption; (c) un economical utilization and (d) excessive

utilization (1) during rapid growth, (2) during illnesses or (3) during pregnancy.

9. Parenteral administration of vitamin A is sometimes indicated.

10. Topical application of vitamin A is of doubtful value. (101 references.)

R. W. Danielson.

Solanés, M. P. **The Vogt-Koyanagi syndrome.** *Anales de la Soc. Mexicana de Oft.*, 1947, v. 5, Jan.-March, pp. 12-23. (See Section 7, Uveal tract, sympathetic disease, and aqueous humor.)

Speas, W. P. **Some allergic manifestations of the eye.** *N. Carolina M.J.*, 1947, v. 8, June, pp. 364-366.

The pathologic ocular manifestations of allergy include angioneurotic edema, blepharitis, conjunctivitis, and keratitis. Iritis, cyclitis, uveitis, endophthalmitis, and retinitis may follow drug therapy. Cataract, sympathetic ophthalmia and scintillating scotoma also may be induced by sensitivity to one or more offending agents. These may be mineral, vegetable or animal in origin. The diagnosis is made by a careful history, the use of skin tests, conjunctival tests, elimination tests and visits to the patients' environment.

Vernal conjunctivitis, the most common allergic ocular manifestation, occurs in the limbic type which is made up of phlyctenule-like vesicles at the limbus, and the palpebral type characterized by severe and persistent granulomas in the upper lid with a heavy viscid mucous discharge. Itching, lacrimation, redness, edema, scaling, and ulceration of the lids are the most common symptoms.

Treatment consists of removal of the offending allergens or of desensitization. General supportive treatment is advised with the addition of calcium.

histaminase, vitamins, and a salt free diet. Irrigations of the eyes with saline solution and the instillation of vasoconstricting drugs and cold compresses offer comfort to the patient.

HYGIENE, SOCIOLOGY, EDUCATION AND HISTORY

Alvaro, M. E. **Organized ophthalmology.** Arch. Chilenos de Oft., 1946, v. 2, July-Oct., pp. 219-225.

The author's address emphasizes the educational value of frequent medical meetings for the exchange of ideas and report of special cases. He commends the standardization of hospitals accomplished by the American College of Surgeons, and advises for the South American countries better undergraduate teaching of ophthalmology and more systematic training of those graduates who intend to follow the specialty.

W. H. Crisp.

Arruga, H. **Drawings of the fundus.** Arch. de la Soc. Oft. Hisp.-Amer., 1947, v. 7, Feb., pp. 117-125.

It is pointed out that illustrations convey more vivid impressions than descriptions, and attention is called to the inaccuracies in the size and position of peripheral lesions in drawings, due to the difficulty of transferring impressions of a concave surface to a flat drawing. Arruga uses water colors applied with a brush, and a spray gun. The combined use of the two methods is described in detail and the results illustrated with the beautiful fundus drawings, for which Arruga is well known. (11 illustrations.)

Ray K. Daily.

Cogan, D. G. **Aims and aids in the teaching of basic sciences in ophthalmology.** Arch. of Ophth., 1947, v. 37, April, pp. 428-432.

A basic science course in ophthalmology should aim primarily to lay a foundation for the appreciation of clinical ophthalmology. The course should be taken by a student just prior to his ophthalmic residency if possible, but in any case not during the residency. It is best that the teaching be done by persons who are actively working in the field of ophthalmology. Such persons are to be found almost exclusively in ophthalmic research centers. In so far as there are few ophthalmic centers with personnel trained in basic sciences, the courses, at present, should be given in only a limited number of places. The classes should be sufficiently large, however, to supply the residents for the many clinical institutions which do not have the basic science facilities.

The following subjects are suggested: anatomy, histology and embryology; physical and physiologic optics; physiology and biochemistry; neuroanatomy and neurophysiology; bacteriology; pharmacology and toxicology; ophthalmic instrumentation.

John C. Long.

Heath, Parker. **Medical assistance at professional level.** Amer. Jour., Ophth., 1947, v. 30, August, pp. 992-994.

Lindner, K. **New things in ophthalmology.** Wien. Klin. Wchnschr., 1947, v. 59, May 2, pp. 265-267.

The author reviews recent progress in a postgraduate course. He stresses the importance of the discovery of Ascher that there are vessels near the limbus filled with clear liquid which flow into the neighboring veins. Pressure on the veins fills these vessels and Schlemm's canal with blood. Bailliard's method of measuring the blood pres-

sure in the central retinal artery and the difference between retinal (and intracranial) pressure on one hand and general blood pressure on the other are discussed. Hruby's accessory lens for investigation of the posterior vitreous with the slitlamp is described. Rieken contributed a method to measure adaptation objectively. The sulfonamides and penicillin enlarged our therapeutic possibilities, the former especially against trachoma and gonorrhoeic ophthalmia, the latter against gonorrhoea and staphylococcal infections. Serpiginous ulcer is effectively treated by rubbing a 20-percent zinc sulfate solution into the cornea. Lindner successfully used Elliot trephining in serpiginous ulcer. The most frequent surgical intervention against glaucoma now is iridencleisis. Desperate cases may respond to cyclodiathermy of Vogt. Cataract surgery advanced with the development of the intracapsular extraction and corneo-scleral sutures. Early removal of infected lenses after perforating injuries is recommended. Shortening operations by excision or partial excision of the sclera aid in certain cases of detachment. Sato describes a method for improving keratoconus by incising the cornea from behind, followed by pressure bandage. Lindner also discusses his new theory of the development of simple as well as high myopia. He bases his theory on the metabolism of the eye during different working conditions, and especially stresses the importance of the extravasation of a tissue-softening serumprotein. These products of the metabolism may be detrimental to the structures of the suprachoroid and sclera which may also have an inherited anatomical weakness.

Max Hirschfelder.

Mercier, A. *Ophthalmology and aviation*. Arch. d'Opht., 1946, v. 6, no. 4, pp. 413-435.

This report is a review of the relationships between ophthalmology and military and civilian aviation. Among the subjects considered in relation to their function in aviation are visual acuity, visual aptitude, night vision, heterophoria, visual fields, effects of acceleration and deceleration on vision, altitude effects, glare, effect of vibration, and chemical intoxications from gasoline vapors, carbon monoxide, and other poisons.

The author discusses in some detail the visual standards for the various classifications of pilots and observers. The bibliography includes 60 pertinent references covering the entire field of aviation ophthalmology.

Phillips Thygeson.

Onfray, R. *Centenary of Edmond Landolt, founder of the Archives d'Ophtalmologie (1846-1926)*. Arch. d'Opht., 1946, v. 6, no. 4, pp. 460-468.

This biographical sketch was inspired by the one hundredth anniversary, on the 17th of May, 1946, of the birth of Aarau Edmond Landolt, one of the great pioneers of ophthalmology. Born in Switzerland, Landolt was the son of a professor of philosophy in a Protestant seminary in Basle. Landolt received his doctorate in medicine from the University of Basle in 1868 and entered Horner's clinic at Zurich the following year. After the War of 1870, in which he took part as a member of the Swiss ambulance service, Landolt studied at Heidelberg with Helmholz, then in Holland with Donders and Snelling. He then migrated to Paris where he very soon became a leader in ophthalmology. In 1882 he founded,

with Panas and Poncet, the Archives d'Ophthalmologie. Author of a great number of ophthalmological studies from 1880 to 1925, he is remembered particularly for the development of numerous optical and surgical instruments and for the surgical treatment of strabismus. He represented the best in French ophthalmology and left an indelible imprint on the science.

Phillips Thygeson.

Roper-Hall, M. J. Research in Zurich. Brit. Jour. Ophth., 1947, v. 31, April, pp. 223-228.

The author presents a summary of the work done at Zurich on the pathologic changes in the aqueous humor and the blood-aqueous barrier. Over 1900 anterior chamber punctures were done on normal and diseased eyes. The origin of the cells, increased in inflammation, was proved to be the blood and neighboring tissues. The predominant role of the reticulo-endothelial system in a great number of cases of chronic uveitis was noted. Albumin was increased in proportion to the number of cells, and in chronic inflammations a dissociation between the albumins and the cells was found, comparable to that observed in abnormal cerebrospinal fluid. Cultures were rarely positive even with strongly positive smears, and tubercle bacilli were found in only one case. Organisms found in the anterior chamber in keratitis and anterior uveitis were of etiologic significance.

The permeability of the blood-aqueous wall was studied with the intravenous fluorescein method. Trauma, uveitis, and most general diseases show an increased permeability; however the findings in glaucoma varied. It was found that the fluorescein test showed more minute changes in the permeabil-

ity of the wall than the Tyndall effect.
O. H. Ellis.

Rusconi, Carlos. Foramina in the orbital cavity of the pre-Spanish aborigenes of Mendoza. Arch. de Oft. de Buenos Aires, 1946, v. 21, Aug., p. 202.

The author studied the anatomy of the orbit in 56 skulls of pre-Spanish aborigenes of Mendoza, Argentina. Several anatomical variations were found, among them an orbital index of 80 to 108.3, the presence of an infra-orbital plate and a supernumerary supraorbital foramen.

Plinio Montalván.

Sbarski, S. I. Ocular war injuries in World War II and the organization of special services in the army. Oftal. Jour. (Odessa), 1946, pt. 3, pp. 36-40.

The following conclusions emerge from an analysis of the ocular injuries in an army hospital for special services. War injuries produce grave ocular damage, and cause blindness in 65 percent of the injured eyes. Surgical procedures at the front comprise closure of the ocular wound, enucleation, and lid repair. The eye service should be organized in connection with other special services, because isolated eye injuries are less frequent than combined injuries. Of the eyes with perforating injuries 40 percent had intra-ocular foreign bodies, and a powerful magnet is indispensable in an army special hospital. Ray K. Daily.

Sorsby, Arnold. Blindness in childhood—past achievements and present problems. J. Roy. Inst. Publ. Health and Hyg., 1947, v. 10, May, pp. 162-172.

Blindness due to neonatal infection and infectious diseases in early childhood has been reduced from 36.4 per

100,000 to 20.2 per 100,000 over a period of 22 years. This is due to the use of chemotherapy and antibiotics such as the Cr  d   technique, sulphonamides and penicillin. The passage of a law requiring a report of any purulent infection in a newborn younger than 20 days is also credited with causing this remarkable improvement.

The present problem is to reduce the causes of blindness due to congenital malformations of genetic origin, dietary deficiency in the mother, intrauterine infections, trauma, and also those caused by biochemical changes. Maternal infection has been underestimated and genetic anomalies are also stressed as causes of blindness in early childhood. (3 tables.)

ANATOMY, EMBRYOLOGY, AND COMPARATIVE OPHTHALMOLOGY

Bein, H. J. Hereditary aplasia of the optic nerve in mice. *Ophthalmologica*, 1947, v. 113, Jan., pp. 12-37.

A famous strain of waltzing mice, kept going by selective breeding, has been under observation at the Department of Anatomy of the University of Basle since 1938. In 1942 the author, in the course of the anatomical examination of an animal from this strain, discovered aplasia of both optic nerves, the chiasm, and both optic tracts. This finding called the author's attention to the occurrence of congenital anomalies of the visual pathway (with or without anomalies of the eyeball or of the ocular adnexa) in waltzing mice. The anatomical findings in three such animals are the basis of the paper under review. Variations as to the degree and extent of the anomaly also occurred. Only a small percentage of the waltz-

ing mice showed gross congenital anomalies of the peripheral or central visual apparatus. The animals with gross anomalies of the visual system did not differ in their behavior from the waltzing animals with normal visual systems. The visually defective ones waltzed with the same endurance, poise and skill as the visually normal animals. Obviously, the congenital anomalies described in the paper did not constitute the specific cause of the waltzing. The presence of congenital visual anomalies could be recognized in vivo by biomicroscopy of the anterior segment of the eye or by ophthalmoscopy. The clinical eye findings will be reported by R. Brueckner. By selective breeding, the author has succeeded in perpetuating the congenital anomaly of the visual system.

Peter C. Kronfeld.

Cooper, E. R. A. The trochlear nerve in the human embryo and fetus. *Brit. Jour. Ophth.*, 1947, v. 31, May, pp. 257-275.

In this very comprehensive article, Cooper attempts to answer three puzzling anatomical questions concerning the trochlear nerve. These are: why does the nerve decussate? Why is the decussation on the dorsal aspect of the brain stem? How does the nerve reach the dorsal position where it decussates? The latter two questions are answered while the first remains unanswered. Through well presented microphotographs of serial sections of numerous embryos from 4 mm. (3 to 4 weeks) onward the embryological processes of the nerve and its nucleus are pictured.

The trochlear nucleus originates in series with the oculomotor nucleus but in the basal plate of the isthmus. As the lateral walls of the isthmus link the metencephalic alar to the mesen-

cephalic basal plates, the basal plate of the isthmus becomes compressed until it assumes a position at the ventral extremity of the lateral wall of the isthmus, and it is here that the trochlear nucleus is situated at first. The fibers from the nucleus immediately form a bundle which turns dorsally at once and thus gains an alar situation in the lateral wall of the isthmus caudally to the superior medullary velum where the decussation occurs. The nerve becomes a compact bundle as it leaves its nucleus and remains so; the decussation is a simple crossing of these two bundles and is not an intermingling of the fibers as in the case of the optic nerves. (11 illustrations.)

Morris Kaplan.

Evans, John N. **The capillary sphincter in the human retina.** *Arch. of Ophth.*, 1947, v. 37, Feb., pp. 182-188.

Microscopic studies of surface preparations of retina and choroid showed a peculiar abrupt narrowing of certain capillaries where they joined the vessel of the next larger order. This narrowing is considered to be of a purely histologic nature due to a sphincter-like action in this region. Some capillaries did not show this narrowing.

If retinal and choroidal capillary sphincters do exist, their contraction would have a powerful effect on the capillary bed. It is conceivable that a derangement of this sphincter mechanism by disturbance of the sympathetic

hormonal relations might be a factor in producing a type of glaucoma simplex. It might seem reasonable to conclude that the retinal capillary aneurysms associated with glaucoma may have their origin in a prolonged constriction of the sphincter muscle. (4 photomicrographs.) John C. Long.

Gartner, Samuel. **Cyclopia.** *Arch. of Ophth.*, 1947, v. 37, Feb., pp. 220-231.

Cyclopia is a congenital anomaly but is not hereditary, since life is impossible. Its development depends on local factors acting on the midline structures of the face at or before the time of development of the anlagen of the eyes. Two cases of cyclops are reported. In one case the eye was a true single median eye; in the other, a fused double eye. The importance of the pigment epithelium in the development of the choroid, as well as its influence on the retina, is indicated by this study. In both cases the absence of pigment epithelium was associated with almost complete absence of the choroid, the choriocapillaris and the lamina vitrea and by maldevelopment of the overlying retina. In one case a misplaced island of retina was observed buried in the choroid and sclera, in an area where pigment epithelium was lacking. Some proof was found that this anomaly was due to metaplastic development of the pigment epithelium into a retinal type of structure. (14 photographs.)

John C. Long.

NEWS ITEMS

Edited by DONALD J. LYLE, M.D.
904 Carew Tower, Cincinnati 2

News items should reach the editor by the 12th of the month

DEATHS

Dr. John Conrad Holzberger, Brooklyn, New York, died May 31, 1947, aged 54 years.

Dr. Olaf Martin Steffenson, Chicago, Illinois, died June 3, 1947, aged 68 years.

Dr. George Loring Tobey, Jr., Boston, Massachusetts, died May 20, 1947, aged 65 years.

Dr. Harry W. Woodruff, Joliet, Illinois, died June 20, 1947, aged 79 years.

ANNOUNCEMENTS

EYE LABORATORY FOR LOS ANGELES

The Estelle Doheny Eye Foundation announces the establishment of an eye laboratory located at St. Vincent's Hospital in Los Angeles, designed to provide certain modern ophthalmic facilities badly needed in southern California.

The immediate functions of the laboratory are:

1. To serve as a pathologic laboratory for the diagnosis and registration of pathologic specimens, with preparation of gross specimens and microscopic slides for ophthalmologists submitting specimens, and for the building up of a museum of eye pathology.

2. To serve as a bacteriologic laboratory where diagnostic scrapings, smears, and cultures can be studied, animal inoculations can be made, and the sensitivity of organisms to various drugs and antibiotics can be determined.

3. To provide facilities for fundus, gross, and slitlamp photography, and to maintain a library of photographs and motion pictures for teaching of ophthalmology.

4. To provide an Eye Bank for southern California, with registry of potential donors and recipients. Donor material will be collected, examined, and distributed, and facilities may later be provided for limited instruction in corneal transplant procedures.

5. To distribute and loan certain drugs and equipment that are not otherwise available in the community.

6. To make available certain special equipment for radiation therapy of the eye for use outside the laboratory.

Dr. Alan C. Woods, professor of ophthalmology, Johns Hopkins Medical School; Dr. Cecil O'Brien, professor of ophthalmology, University of Iowa Medical School; and Dr. Phillips Thygeson, formerly professor of ophthalmology, Columbia University, and now associate professor of ophthalmology, University of California, will serve on the advisory board. Dr.

A. Ray Irvine, professor of ophthalmology, University of Southern California, will act as chairman of the original board. It is contemplated that the advisory board will also include prominent business and professional leaders as well as representatives from the eye departments of local hospitals, medical schools, and the Eye Section of the Los Angeles County Medical Society.

Dr. Peter Soudakoff, formerly associate professor of ophthalmology at the Peking Union Medical College, will serve as full time pathologist at the laboratory. It is planned that, as part of the residency program of the eye service of the Los Angeles County Hospital and certain local veterans' hospitals, that each resident will spend 2 or 3 months at the laboratory. It is anticipated that a research associate, granted a Fellowship in basic ophthalmic research by the Foundation, will be added to the laboratory staff from time to time.

In creating this perpetual charitable Foundation dedicated to the conservation and restoration of eyesight, Mrs. Edward Laurence Doheny, with great generosity and discerning wisdom, has been careful to insure a flexibility of organization to take care of the immediate practical needs and at the same time provide for eventual development of much needed research in ophthalmology.

GILL HOSPITAL GRADUATE COURSE

The Gill Memorial Eye, Ear, and Throat Hospital, Roanoke, Virginia, announces that its 21st annual spring graduate course in ophthalmology and otolaryngology will be held from April 5 through April 10, 1948.

Among the guest speakers in ophthalmology will be Prof. Adalbert Fuchs, UNRRA-WHO Shanghai, China; Dr. Conrad Berens, New York; Dr. A. D. Ruedemann, Wayne University Medical School, Detroit; Dr. Edwin B. Dunphy, Massachusetts Eye and Ear Infirmary, Boston; Dr. Trygve Gundersen, Boston; Dr. John M. McLean, New York; Dr. Alston Callahan, Medical College of Alabama, Birmingham.

MISCELLANEOUS

DARTMOUTH EYE INSTITUTE CLOSES

The Dartmouth Eye Institute, Hanover, has terminated all clinical activities "because of an inability to provide a sound financial basis for future activities," the managing trustee, John Pearson, has announced. The clinic was es-

published in 1921 when Prof. Adelbert Ames, Jr., undertook the study of problems of visual optics. The current work of Professor Ames in visible perception continues under the auspices of the Hanover Institute.

UNIVERSITY OF CINCINNATI APPOINTMENT

The University of Cincinnati College of Medicine has appointed Dr. Donald J. Lyle professor of ophthalmology and director of the Cincinnati General Hospital's Department of Ophthalmology.

STUDY OF CONGENITAL MALFORMATIONS

In an effort to collect more precise data on the relationships between certain maternal infections and congenital malformations, a nationwide study is being sponsored by the American Academy of Pediatrics and the National Society for the Prevention of Blindness. Questionnaires are being sent to obstetricians, ophthalmologists, and pediatricians, seeking the reporting of cases of German measles in expectant mothers and of children with congenital defects that might be attributed to other infections in the expectant mother, such as measles, chicken pox, mumps, and influenza.

Although an association has been established between the occurrence of German measles early in pregnancy and certain congenital defects in the offspring, information is lacking as to the frequency with which this happens and as to the possible influence of other communicable diseases that might have been contracted by the expectant mother.

Data will be studied by the following committee: Dr. Herbert C. Miller, professor of pediatrics, University of Kansas Hospitals, Kansas City, Kansas; Dr. Stewart Clifford and Dr. Clement A. Smith, both of Boston, Massachusetts; Dr. Josef Warkany, of Cincinnati, Ohio; Dr. James Wilson, of Ann Arbor, Michigan; and Dr. Herman Yannet, of Southbury, Connecticut. Physicians knowing of cases are urged to register them with Dr. Miller, chairman of the committee.

SOCIETIES

CENTRAL ILLINOIS MEETING

The eighth meeting of the Central Illinois Society of Ophthalmology and Otolaryngology was held at the Abraham Lincoln Hotel, Springfield, Illinois, on August 23rd and 24th. Mr. J. C. Copeland of the Riggs Optical Company, Chicago, gave four talks on: "Practical Session in Retinoscopy," "Practical Applications of the Spherical Equivalent Concept," "Methods of Overcoming Some Difficulties in Cross Cylinder Testing," and "Duochrome Refraction Methods." Other speakers were: Dr. Philip R. McGrath, Peoria, Illinois, who spoke on "Retrolbulbar

Neuritis;" Dr. French K. Hansel, St. Louis, Missouri, "Allergy in Ophthalmology and Otolaryngology;" and Dr. Carson Gabriel, Quincy, Illinois, "Case Reports: Carcinoma of the Lung and Complete Atelectasis of Lung."

SEMINAR ON INDUSTRIAL VISION

A familiarization seminar on Industrial and Occupational Vision will be held the afternoon and evening of November 5, 1947, at the Van Cleve Hotel, Dayton, Ohio. The seminar is being sponsored by Zone 9, Ohio State Optometric Association and the Safety Council, Dayton Chamber of Commerce. The program will include:

2:30 P.M.—Introduction to theme—Occupational Vision; F. E. Billette, O.D., governor, Zone 9; R. N. Roth, O.D., seminar chairman.

3:00 P.M.—Accident Proneness and The Employee's Vision; N. C. Kephart, Ph.D., Assistant professor of Industrial Psychology, Purdue University.

3:30 P.M.—Industry and Seeing—One Aspect of Occupational Seeing; Joseph H. Tiffin, Ph.D., professor of Industrial Psychology, Purdue University.

4:00 P.M.—The Nurse in The Industrial Vision Program—Hazel H. Leedke, R.N., industrial nurse, Health Department, Thilmany Pulp and Paper Company, Kaukauna, Wisconsin.

4:30 P.M.—The Utilization of a Program of Employee Visual Classification, Correction, and Placement Within Our Plant. Richard Wampler, safety director, the Dayton Rubber Manufacturing Company.

5:00 P.M.—Some Aspects of a Plant Safety Goggle Program. William Carroll, director, Industrial Vision Department, White-Haines Optical Company, Columbus, Ohio.

The meeting is open to representatives of industry, and all members of the ophthalmic professions are invited to attend. A registration fee of five dollars per person will include the dinner. For registration write to R. N. Roth, O.D., 2324 Salem Avenue, Dayton 6, Ohio.

PERSONALS

ACCEPTS YALE APPOINTMENT

Dr. J. Alexander van Heuven, formerly of Utrecht, Holland, has been appointed assistant clinical professor of ophthalmology at the School of Medicine, Yale University. Dr. van Heuven will be associated in private practice with Dr. Eugene M. Blake, head of the department.

MOVES TO NEW OFFICES

Dr. Clement C. Clarke announces the removal of his offices to 240 Bradley Street, New Haven 10, Connecticut.

VITREOUS INFECTIONS AND STREPTOMYCIN*

EXPERIMENTAL STUDIES

IRVING H. LEOPOLD, M.D., MARJORIE WILEY, B.A.,
AND RICHARD DENNIS, M.D.
Philadelphia, Pennsylvania

Vitreous infections are fortunately not frequent. Nevertheless, they do occur and are extremely difficult to treat. They may occur as a result of bacteria spreading from other parts of the body or eye, following penetrating or perforating injuries, and after intraocular surgery. With the advent of the sulfonamides and penicillin impetus was given to experimental studies concerning vitreous infections.¹⁻³

There are certain principles that must be followed in treating vitreous infections with an antibacterial drug. In order for any chemotherapeutic agent to be effective it must be able to reach the infected tissue in adequate concentration. The organism responsible for the infection must be susceptible to the chemotherapeutic agent. When the therapeutic drug is present in the infected tissue in adequate concentration, it should not produce damage to the tissue.

Systemically administered sulfonamides will reach the vitreous humor in high concentrations⁴⁻⁷ and in such concentrations will not damage the vitreous body. However, when tried in a standard experimental infection, systemically administered

sulfonamide therapy usually failed.^{2,8,9} Direct intravitreal injections of sulfonamides as employed by von Sallmann and co-workers¹ were not successful in controlling experimental vitreous infections. There are, however, a few reports of direct intravitreal injections of sulfonamides controlling infection in human eyes.¹⁰ Direct intravitreal injections of sulfonamides produce vitreous, retinal, and choroidal damage.^{8,11}

Penicillin has been shown to penetrate poorly from the blood stream into the vitreous humor^{3,12-16} of the normal and inflamed eye. Corneal baths, corneal iontophoresis, subconjunctival and anterior-chamber injections produced higher intravitreal concentrations of penicillin than did the systemic route.^{3,12,13} However, although these local measures and massive systemic doses had some success in controlling experimental vitreous infections, not one was as effective as direct intravitreal injections of penicillin.^{1-3,16,26}

Direct intravitreal injections of penicillin occasionally produced vitreous opacities, retinal and choroidal degeneration around the sites of injections. Some eyes, so injected, showed only temporary alterations of structure similar to those following normal saline injections. Clinical cases are beginning to appear in the literature in which vitreous infections have been successfully treated by direct injections without producing untoward dam-

* Presented before the Section of Ophthalmology, College of Physicians of Philadelphia, April 24, 1947. From the Department of Ophthalmology, University of Pennsylvania, and Harrison Research Surgery Department, University of Pennsylvania. Streptomycin used in this study was supplied by Merck & Co., Rahway, New Jersey.

age.¹⁷ In some hands, experimental intravitreal penicillin injections have proved quite damaging, but this has been attributed to an impure form of penicillin.¹⁸ Five thousand units of purified penicillin in 0.1 cc. of water have been placed in the vitreous with little subsequent reaction and no ophthalmoscopically visible

changes.²⁶ Because of the possibility of damaging the intraocular structures of the posterior segment with commercially available penicillin, ophthalmologists hesitate to use such therapy. Less damaging procedures are usually tried first and intravitreal injection used only as a final hope.

Because it has been shown that streptomycin penetrates poorly from the blood stream into the normal vitreous humor,¹⁹ it is likely that local administration of streptomycin will have to be used in therapy of vitreous infections. Studies of vitreous-humor concentrations following local methods of administration of streptomycin have not as yet been reported, and are included in this present paper.

EXPERIMENTAL STUDIES

PART 1

Streptomycin was administered subconjunctivally. It was also injected directly into the anterior chamber and directly into the vitreous humor. Blue-eyed chinchilla rabbits weighing between 3 to 4 kilos were used. Six normal eyes were used for each type of injection. Subconjunctival injections were made with 100,000 micrograms/0.2 cc. of normal saline and vitreous injections with 100,000 $\mu\text{g.}/0.1 \text{ cc.}$

Direct anterior-chamber injections were made with 100,000 $\mu\text{g.}/0.1 \text{ cc.}$ The anterior chamber was punctured and approximately 0.1 cc. of aqueous humor was drawn into the syringe containing 100,000 $\mu\text{g.}$ in 0.1 cc. and approximately 0.1 cc. of the syringe mixture was reinjected into the anterior chamber. In this way approximately 50,000 $\mu\text{g.}$ were placed into the anterior chamber.

Vitreous humor specimens for each type of administration were withdrawn at 30 minutes after injection in three eyes and after two hours in three eyes. Specimens were analyzed by the method described by Stebbins and Robinson²⁰ using their strain of staphylococcus aureus.

The results of these studies are recorded in Table 1. It is evident that anterior-chamber injections produce higher concentrations than the subconjunctival route⁸ in the vitreous humor of the normal eye. This had been shown previously to occur with penicillin.³ All these methods of local administration of streptomycin produced higher intraocular concentrations than those reported for the usual systemic doses.¹⁹

Subconjunctival injection was always followed by marked local injection and chemosis that largely subsided in 8 to 12 hours. Anterior-chamber injection produced conjunctival edema, pericorneal in-

jection, and signs of iritis. Most of these changes disappeared in 36 to 48 hours. In one rabbit, lenticular opacities developed. Because of these lens changes the anterior chambers of six additional eyes were injected with concentrations of streptomycin ranging from 5,000 to 100,000 units per injection. Care was taken not to inject the material with excess force and to be certain that the needle did not touch the lens. In none of these did any permanent lens changes develop.

Posterior-segment injections were made with concentrations ranging from 40 to 100,000 $\mu\text{g.}$ in 0.1 cc. into 12 rabbit eyes. The results are listed in Table 2. All produced clouding of the vitreous humor. The globe became red and vitreous opacities developed. Slight clouding of the cornea occurred temporarily for a few hours after each injection and was probably due to a temporary increase in intraocular pressure. After two days large white areas could be seen in the retina around the site of injection in all six eyes that received 5,000 to 100,000 units per injection. These were areas of retinal and choroidal exudation which gradually changed to patches of degenerated tissues. These patches were localized to the side of the original site of injection except in the eye that received 100,000 units. Here the entire posterior segment was involved, preventing a view of the fundus.

It is thus apparent that intravitreal injections of streptomycin produced damage similar to that seen with penicillin. However, it is noteworthy that concentrations below 800 $\mu\text{g.}$ of streptomycin can be injected with very little subsequent reaction similar to that seen following the injection of normal saline alone.

Anterior-chamber injection of streptomycin produced no permanent damage and did provide levels that might prove helpful in controlling vitreous infections. Anterior-chamber injections of penicillin

TABLE 2
RESULTS OF POSTERIOR-SEGMENT INJECTIONS
OF VARIOUS CONCENTRATIONS

Rabbit No.	Micrograms of Streptomycin per Injection	Ocular Reaction
1	100,000	Exudation and later organization of posterior segment No fundus view
2	50,000	Exudation and later degeneration of retina and choroid on side of injection
3	20,000	Exudation and later degeneration of retina and choroid on side of injection
4	10,000	Exudation and later degeneration of retina and choroid on side of injection
5	10,000	Exudation and later degeneration of retina and choroid on side of injection
6	5,000	Exudation and later degeneration of retina and choroid in quadrant of injection
7	3,000	Exudation and later degeneration of retina and choroid in quadrant of injection
8	1,500	Exudation and later degeneration localized about site of injection
9	800	No reaction except immediately at site of injection
10	400	No reaction except immediately at site of injection.
11	200	Slight exudation in addition to damage at site of injection
12	40	No reaction except for damage at site of injection

were not as successful in controlling experimental vitreal infections as the direct intravitreal injection technique.³ One hesitates to disturb the integrity of an eye by any sort of intraocular injection unless he is certain that the diagnosis is correct, that the infection will respond, and that matters will not be made worse by such therapy. Corneal iontophoresis and subconjunctival injection can give high concentrations in the anterior chamber but not as high as those reached by direct anterior-chamber injection. It apparently requires very high anterior-chamber concentrations of drugs such as streptomycin and penicillin in order for them to pass posteriorly through the iris-lens barrier. In an effort to find another method by

which these antibiotics could reach the vitreous without direct intraocular injection, further studies with iontophoresis were undertaken.

0	0	.3	.4

It is known that ions do not pass through circulating fluid and it is assumed that they are carried away by such fluid. This explanation has been applied to the vascular sponge of the choroid. It had been accepted generally that ions could not be introduced into the posterior segment of the eye through the choroid.^{21, 22} However, this hypothesis has been disproved recently by von Sallmann.^{23, 24} He reported driving anions through the sclera, choroid, and retina into the vitreous. For these reasons studies were run to determine the ability of penicillin and streptomycin to penetrate the posterior segment of the eye when aided by iontophoresis.

PART 2

Instead of applying electrodes directly to the sclera, the antibiotics were injected retrobulbarly and a glass electrode was applied over the corneal surface. The corneal electrode was filled with normal saline and the positive pole attached to it. The negative electrode was placed behind the neck. These poles were reversed for streptomycin. A current of 3 to 5 milliamperes was applied for five minutes and the vitreous humor specimens withdrawn

for analysis at 30 minutes and two hours. Penicillin analyses were done by the technique described by Rammelkamp,²⁵ and streptomycin according to the Stebbins and Robinson²⁰ method. Fifty-five thousand units of penicillin in 2 cc. of saline were injected retrobulbarly and 200,000 units of streptomycin in 2 cc. of saline. The results are recorded in Tables 3 and 4.

It is evident that retrobulbar injection

plus iontophoresis did aid the penetration of each antibiotic into the vitreous humor.

The levels for streptomycin are approximately the same as those following anterior-chamber injection (see table 1). Vitreous concentrations of penicillin were likewise similar to those reached by anterior-chamber injections according to an earlier report.³ Following retrobulbar injections considerable chemosis and injection of the globe occurred. This reaction subsided within 8 to 12 hours. Iontophoresis of the duration and strength used produced slight, temporary clouding of 5 of 16 corneas but no permanent change.

PART 3

To determine the relative efficiency of these methods against vitreal infection the following studies were undertaken: 0.1 cc. of a diluted 18-hour broth culture of *B. coli* (100,000 organisms per cc. in-

TABLE 5

VITREOUS INFECTIONS DUE TO 1,000,000 BACTERIA-COLI ORGANISMS AS INFLUENCED BY VARIOUS FORMS OF LOCAL STREPTOMYCIN THERAPY

Type of Therapy	No. of Eyes	No. of Eyes Degenerated in 3 weeks	No. of Eyes Degenerated in 4 months
1. No Therapy	6	6	
2. Intravitreal Injection	6	0	6
3. Anterior-Chamber Injection	6	2	4
4. Retrobulbar Injection	6	6	
5. Retrobulbar Injection plus Iontophoresis	6	0	6

hibited by 3 μ g. of streptomycin per cc.) was injected into the vitreous humor of 30 eyes. There were approximately 1,000,000 organisms in each injection. Within 30 minutes after injection of the organisms, 100,000 μ g. of streptomycin in 0.1 cc. were injected into the vitreous of six eyes. Six eyes received 100,000 μ g. of streptomycin in the anterior chamber. Twelve eyes were injected retrobulbarly with 200,000 units of streptomycin in 2 cc. of saline. Six of the eyes with retrobulbar injections of streptomycin were treated also with iontophoresis. The negative pole was placed on the corneal glass electrode as in the experimental studies mentioned above. The same current and time for iontophoresis were used as in the preceding experiment. Six eyes had only injections of the organism and no streptomycin therapy. All eyes received daily atropine drops to facilitate ophthalmologic examination.

These studies were then repeated using 20,000 organisms per injection.

(table 6). Six eyes were used for each type of therapy and six received no streptomycin.

The untreated eyes receiving 1,000,000 organisms showed marked vitreous abscesses in 16 hours that extended rapidly into the anterior chamber and caused complete degeneration of the eye within 2 to 3 weeks. The untreated eyes that received approximately 20,000 organisms showed vitreous abscesses that spread to the anterior segment in 5 to 7 days and gradually degenerated to phthisis bulbi in 4 to 5 weeks.

Not one of the treated eyes that received 1,000,000 organisms recovered (see table 5). Those that were injected directly into the vitreous with the streptomycin showed a fairly localized vitreous abscess for the first 5 to 7 days but these gradually extended and the eyes degenerated slowly during the next four months.

The six eyes treated with retrobulbar injections of streptomycin alone were completely degenerated within 2 to 3

TABLE 6

VITREOUS INFECTIONS DUE TO 20,000 BACTERIA-COLI ORGANISMS AS INFLUENCED BY VARIOUS FORMS OF LOCAL STREPTOMYCIN THERAPY

Type of Therapy	No. of Eyes	No. of Eyes Degenerated in 5 Weeks	No. of Intact Quiet Eyes after 4 months
1. No Therapy	6	6	0
2. Intravitreal Injection	6	0	6
3. Anterior-Chamber Injection	6	0	3
4. Retrobulbar Injection	6	6	0
5. Retrobulbar Injection plus Iontophoresis	6	0	4

weeks. The six eyes treated with retrobulbar streptomycin injections plus iontophoresis showed localized vitreous abscesses for the first week and then gradually degenerated within the next 5 to 6 weeks.

Eyes treated with anterior-chamber injections varied. Three of the eyes required 5 to 6 weeks for degeneration and three degenerated within 2 to 4 weeks.

In the eyes infected with 20,000 organisms, intravitreal injection controlled all six so treated. These all showed vitreous abscesses that did not extend but remained localized and subsequently organized allowing only a partial view of the fundus. The vitreous never completely cleared but after four months the anterior segments were clear and the globe maintained its form and intraocular pressure.

Four of the eyes treated with retrobulbar streptomycin plus iontophoresis showed a partial fundus view, an intact globe, and quiet anterior segment after four months. The other eyes were soft and degenerated by the fourth month. None of the eyes treated with retrobulbar streptomycin alone differed from the control eyes.

Three of the eyes that received streptomycin in the anterior segment were still intact after four months but only a narrow view of the fundus could be obtained. The anterior segment was quiet and the intraocular pressure not lowered. One eye maintained its shape and intraocular pressure and had a clear anterior segment. Aside from a faint red reflex, no fundus details could be seen in this eye. The other eyes degenerated within two months.

These results indicate that intravitreal injection, retrobulbar injection plus iontophoresis, and anterior-chamber injection of streptomycin all lessened the severity of the infectious process. When fewer organisms were used, these forms

of therapy were more successful. In this small series, direct intravitreal injections of streptomycin were superior to the other methods. Retrobulbar streptomycin plus iontophoresis was slightly better than direct anterior-chamber injection.

Although these results are not absolute, they do suggest that retrobulbar streptomycin plus iontophoresis may aid in controlling vitreous infections.

The experimental data concerning vitreous infections shows that the best results are obtained when therapy is instituted early^{1, 2} before the infection can become firmly established and the vitreous disorganized. In eyes in which there is a doubt concerning the severity of the posterior-segment infection, when one cannot be certain that the vitreous infection will be overwhelming, one may hesitate about using direct intravitreal injection of an antibiotic because of the possible damage from such an injection.

In such eyes some form of local administration of penicillin or streptomycin should be employed. One should not rely solely on massive systemic doses of penicillin or streptomycin.²⁷ The local routes that may be employed are subconjunctival injection, anterior-chamber injection, and retrobulbar injection plus iontophoresis.

It must be pointed out that these procedures have not been tried in human eyes. Also, not one of these forms of therapy was repeated in the above experiments. It is possible that daily repetition of anterior-chamber or retrobulbar injection plus iontophoresis may have been more effective.

CONCLUSIONS

1. Retrobulbar injections of streptomycin and penicillin plus iontophoresis produced vitreous-humor concentrations equal to that reached with direct anterior-chamber injections and superior to those

following subconjunctival injection.

2. Direct intravitreal injection of streptomycin, retrobulbar injection plus iontophoresis, and anterior-chamber injections reduced the severity of experimental vitreous infections due to bacteria coli. They were effective in the order listed.

3. Direct intravitreal injections of streptomycin produced retinochoroidal exudation and subsequent degeneration. In concentrations below 800 μ g. per injection, the damage was minimal and limited to the site of injection.

PIGMENTATION OF THE PALPEBRAL CONJUNCTIVA RESULTING FROM MASCARA*

ALGERNON B. REESE, M.D.
New York

Several years ago, during the course of a routine examination of a middle-aged woman, a granular, stippled pigmentation was noted under the palpebral con-

months, the condition showed no appreciable change and a drawing was made (fig. 1). The pigmentation was situated at each extremity of the tarsus on a level

Fig. 1 (Reese). A stippled pigmentation situated at each extremity of the tarsus on a level with its upper border.

junctiva of both upper lids. The nature of the lesion was not known and no clue was obtained as to its cause. After 10

with its upper border. It was located under the conjunctiva rather than in the conjunctiva. Over the pigmented area there was a folliculosis and slight congestion. The condition was identical in both lids. After 2½ years, there had been some extension of the pigmentation and another drawing was made (fig. 2). At each extremity of the tarsus, and particularly at the temporal end, the pigmented area had broadened and had extended horizontally so that it could be seen as a narrow line along the upper border of the tarsus, fading out in the central portion. In addition, a mottled, deep-seated, bluish-black pigmentation could be seen rather faintly under the conjunctiva of the lower lid.

During the period this case has been followed, six additional cases have been observed. Except for minor variations they have all been of similar pattern.

* Read at the 82nd annual meeting of the American Ophthalmological Society, San Francisco, California, June, 1946.

The location is always the same, varying only in that some are more pronounced at each extremity of the tarsus (fig. 3), and particularly the temporal extremity, while others manifest themselves mostly along the upper border of the tarsus. The color varies from black to a dirty light brown. The pigment is situated under the conjunctiva and always has a granular appearance. Under higher magnification it can be resolved into irregular punctate dots. There is always an associated folliculosis. The symptoms referable to the condition are mild if any. Symptoms that the patients gave having possible connection with the lesion are: burning, redness, and itching of the eyes, feeling of sleepiness, roughness and swelling of the lids, and desire to blink the eyes excessively. All of the patients were women ranging in age from 31 to 55 years.

Biopsy material was removed from the most marked case (fig. 3) at a site lateral to the tarsus. The hematoxylin and eosin stain (fig. 4) showed accumulations of black amorphous pigment in follicles and in the stroma under the follicles. The pigment granules were located in or upon stroma cells or were free in the tissue. They were not in macrophages or giant cells and therefore had excited no foreign-body reaction. There was no pigment in the conjunctiva, and no granules could be detected making their way through the epithelium. The follicles were composed of lymphocytes and plasma cells. Bleached sections (fig. 5) showed the pigment unaffected. Sections on which the Turnbull stain was employed showed that the pigment contained no iron.

Fig. 2 (Reese). The same case as shown in Figure 1 after $2\frac{1}{2}$ years. There is an increase in the pigmentation at each extremity of the tarsus, particularly on the temporal side. The pigmentation has also extended horizontally as a narrow line along the upper border of the tarsus fading out in the central portion. In addition, there is a mottled, deep-seated, bluish-black pigmentation faintly seen under the conjunctiva of the lower lid.

In an attempt to determine the nature of this lesion, consideration was given to various types of pigmentation of the conjunctiva. Congenital melanosis or acquired precancerous melanosis would not be sym-

Fig. 3 (Reese). This shows the characteristics of the lesion in the most marked case encountered. The biopsy material was taken from the temporal extremity of the tarsus.

Fig. 4 (Reese). A hematoxylin and eosin stain of biopsy material from the case shown in Figure 3. In the follicles composed of lymphocytic and plasma cells and in the stroma under the follicles, there are accumulations of black-pigment granules in or around stroma cells or free in the tissue.

Fig. 5 (Reese). A bleached section of the biopsy material showing the pigment unaffected.

metrical and bilateral and, furthermore, the fact that the pigment is not melanin is indicated by the histologic sections which show, among other things, its failure to bleach. It is not hematogenous pigment because the Turnbull stain showed the absence of iron, and there is no known source of extravasated blood or hemolyzed blood from some systemic condition. Ectogenous or endogenous ochronosis cannot be seriously considered because the location of the pigmentation is not at an exposed site; there is no history of contact with any of the phenol group, no hereditary history, and no alkaptonuria. The condition is not argyrosis because there is no history of local use or ingestion of silver. Furthermore, the location and appearance are not consistent with argyrosis, and the sections rule it out. There is no history to support the occurrence of pigmentation from the long use of adrenalin (I have seen two such cases and they showed jet-black punctate deposits under the palpebral conjunctiva of the lower lid). In the cases reported here, there is no evidence of Addison's disease, no history of exposure to or the use of arsenic, gold, iron, aniline products, indelible substances, or colored inks.

All of the patients were women, five of whom admitted the constant use of mascara and one of whom denied its use so vehemently as to become suspect. One was on the stage and used a great deal of make-up. Off the stage she used, in addition to mascara, eye shadow on the skin of the upper lid. On the stage a process called "beading" was included in her make-up. This consisted of putting a heated black wax on the lashes. She stated that this invariably got in her eyes.

According to the best references I could obtain, mascara is composed of the following:

	Percent
Glyceryl monostearate	10

Triethanolamine	3
Stearic acid	15
Petrolatum	20
Gelatin	2
Water	17
Beeswax	25
Prepared lamp black	8

The appearance and staining reactions of the pigment in the biopsy sections are consistent with its being lamp black. However, there is some evidence that the pigment did not exist as such in the mascara but was precipitated in the tissue. This evidence is the lack of pigment in or adjacent to the epithelium, its location well under the epithelium and sometimes quite deep in the stroma, its close relation to the stroma cells and the tissue interstices, and the absence of a foreign-body type of reaction. If the pigmentation discussed here occurs as the result of precipitation in the tissue, it would be comparable in this respect to the pigmentation from silver which, however, has a predilection for the elastic fibers.

If mascara is the source of the pigmentation, then there must be some individual contributing factor, because everyone who uses mascara does not develop a pigmentation. Only two of the patients considered themselves allergic. The constant presence of follicles is consistent with an allergic reaction but eosinophiles are absent. The use of no one brand of mascara was common to all the patients.

It is concluded that the pigmentation of the palpebral conjunctiva described here results from the use of mascara or allied pigment-bearing cosmetics but that there is some factor peculiar to the individual determining its occurrence.

As women using mascara would, no doubt, consider this pigmentation and its possible attending mild symptoms a cheap price to pay for allure and glamour, the treatment, which is to stop the use of mascara, is probably of no avail

ACUTE REVERSIBLE CATARACT IN CHICKEN DUE TO VARIOUS NITROCOMPOUNDS*

WILHELM BUSCHKE, M.D.[†]

New York

Since the early clinical reports 12 years ago by Horner, Boardman, Cogan, and others on cataracts after prolonged intake of dinitrophenol, an extensive clinical literature on this cataract has accumulated. Horner reviewed this literature in 1942.¹ An identical type of cataract was described due to intake of dinitrocresol which had been used in Scandinavia for weight reduction.²

According to Horner, only 0.86 percent of all individuals who have ingested dinitrophenol are afflicted with cataract, and no correlation to the amount of drug taken, nor to the duration of time during which it had been taken, nor to the age of the patient could be established. In view of the low incidence, it is of interest that this cataract has been described in successive generations of a family,³ and that some years ago dinitrophenol cataract was seen in the Wilmer Institute in a pair of identical twins. This suggests that a genetic predisposition plays an important role in the susceptibility to this cataract. This notion is strengthened by the fact that in spite of extensive ex-

periments of long duration by many authors it has been found impossible to produce dinitrophenol cataract experimentally in various other species; namely in rats, rabbits, guinea pigs, and dogs, although Bettman⁵ observed D.N.P. cataract in a special strain of mice. In contrast to the unsuccessful experiments in various other species, Robbins was able to produce experimental D.N.P. cataract in baby ducks and baby chicks with close to 100-percent results, although the upper age limit for the susceptibility was rather low.⁴ These observations have been essentially confirmed and somewhat extended by Bettman,⁵ while Dietrich and Beutner⁶ failed to produce cataracts with two mononitrophenols in chicks with Robbins' procedure.

Recently, Petty and Martin¹² observed some slowing of the onset of D.N.P. cataract by thiouracil, but they could not lower the incidence of its occurrence.

In addition to the obvious genetic predisposition, the complexity of the pathogenetic problem is illustrated by the facts (1) that the D.N.P. cataract in birds develops acutely in contrast to the chronic cataract in human beings, and (2) that it is, according to Bettman, and to my own observations, reversible even in spite of the continued intake of the drug. It appeared to be desirable to pursue the experiments on chicks more systematically because the regular susceptibility of this species would promise to provide some foothold on the pathogenesis of this cataract.

The following experiments were designed to standardize the conditions for the experimental production of the D.N.P. cataract, to test related com-

*From the Wilmer Ophthalmological Institute of the Johns Hopkins Hospital. This work was supported in part by the John and Mary R. Markle Foundation. Read at the 16th scientific meeting of the Association for Research in Ophthalmology, Inc., Atlantic City, June 10, 1947.

[†] Present address: Ayer Foundation Ophthalmic Research Laboratory, Manhattan Eye, Ear, and Throat Hospital, New York.

I am indebted for the supply of some of the compounds used in this study to Dr. L. B. Hellerman, department of biochemistry, Johns Hopkins Medical School; Dr. D. E. Kvalnes, E. I. Du Pont Company, Wilmington, Delaware; and Dr. Guggenheim, Hoffman-LaRoche Company, Basel, Switzerland.

The drawings of Figures 1, 1a, 2, and 2a were made by Mrs. A. S. Burgess.

pounds for their cataract-producing capacity, and to correlate the occurrence of the cataract with other biologic and metabolic effects of these compounds. While the first two of these approaches yielded interesting observations, the latter one—that is, the correlation with other effects of the drug—is so far in a quite fragmentary state.

Robbins produced the cataract by mixing dinitrophenol with the diet fed to the animals. My preliminary experiments with varying concentrations of 2, 4-D.N.P. in the diet showed that the occurrence of cataract was dependent on the amount of D.N.P. ingested over a given period of time, and that the threshold concentration of D.N.P. in the diet of baby chicks was 0.1 percent.

The standard procedure then adopted was the administration of the compound as a 0.2- to 0.4-percent solution in peanut oil (with a few compounds in water) in a single dose by stomach tube or intramuscularly. With this procedure, cataracts developed promptly after 1 to 1½ hours in any number of different strains I have tested. The threshold dose is 20 micrograms (1/50 of a mg.) per gm. bodyweight. Cataracts developed promptly also in adult chickens with this procedure, and the failure to produce cataracts in older animals with the ordinary feeding technique in the diet may be due to the fact that older animals have a relatively smaller food intake, in relation to their bodyweight, than young ones.

The first opacities are seen around the suture lines at the anterior pole of the lens (fig. 1) but, after a few hours, the anterior and posterior cortex become diffusely opaque. The suture lines at the anterior pole often gape in an early stage. Under the dissecting microscope, the lens fibers surrounding the anterior pole have a brittle appearance, and innumerable minute structures with the appearance

Fig. 1 (Buschke). Beginning dinitrophenol cataract in chick, with gaping suture lines at anterior pole.

Fig. 1a (Buschke). Appearance of lens under dissecting microscope in early dinitrophenol cataract of chick.

of tiny vacuoles are seen. I could not decide whether these vacuoles were inside or surrounding the individual lens fibers (fig. 1a). With doses with which the animals survive, the lenses become spontaneously clear again after about 24 hours. With the disappearance of the anterior opacities the posterior opacities become more clearly visible (fig. 2).

In feeding experiments, the lenses become clear again with suitable doses after a few days even in spite of continued presence of the drug in the diet. However, systematic experiments have not as yet been done with repeated chronic application of the drug by injection and, therefore, it cannot be excluded, at present, that the spontaneous recovery in continued feeding experiments may be

Fig. 2 (Buschke). Posterior polar lens opacities seen during recovery period from dinitrophenol poisoning in chicken. (Composite drawing.)

Fig. 2a. (Buschke). Appearance of lens opacities, in the same stage as shown in Figure 2, as seen in the narrow beam of the slitlamp.

due to a diminished food, and thus drug, intake.

Attempts to produce the D.N.P. cataract in vitro had, similar to Bettman, essentially negative results. Whole eyes or removed lenses were kept in varying concentrations of D.N.P.—sodium salt in Tyrode's solution or beef aqueous, or the solutions were injected into the vitreous of the enucleated eye after removal of some intraocular fluid. In none of these experiments were the opacities which developed of the same degree as those in living animals, and, in fact, they were

not significantly different from the controls. Eyes were also removed 40 minutes after systemic, in vivo, poisoning of chicks with D.N.P. and stored in a moist chamber at body temperature; some opacities developed in the lenses of the enucleated eyes, but even here they seemed to be less extensive than in vivo. It appears, therefore, that some factor other than or in addition to D.N.P. is required for the development of the cataract, and that this additional factor is manufactured elsewhere in the body. This aspect requires further experimental study.

In order to test the possibility that the cataract may be due to dehydration, distilled water was instilled at frequent intervals during the period of poisoning; this, however, did not inhibit the development of cataract. If lenses after development of the opacities were removed and immersed in Ringer's solution of varying dilutions, the opacities cleared partially within a few hours, but this clearing process was not more marked in the lesser concentrations than it was in the higher salt concentrations. There is, then, no evidence that the cataract is produced by dehydration due to increased tonicity of the surrounding fluids.

With the peroral or intramuscular technique of administration, 37 compounds chemically related to dinitrophenol were tested in varying amounts for their cataract-producing capacity. With many of these compounds, the rectal temperatures of the chicks were recorded for several hours after poisoning, and the oxygen consumption of the animals was recorded in a respiration chamber after Tainter and Rytand.⁷ The respiration chambers were kindly loaned by Dr. E. K. Marshall, Jr., department of pharmacology of the Johns Hopkins Medical School. The results are summarized in the following tables.

The following groups of compounds were tested and classified according to the modification of radicals attached to the benzene ring.

TABLE 1

GROUPS OF COMPOUNDS TESTED AND CLASSIFIED

2,4-DINITROPHENOL

I

IMPORTANCE OF PRESENCE, NUMBER AND POSITION OF NITRO-GROUPS:

Other DN-Phenols
Mono-Nitrophenols
Halogen-Phenols
Carboxy-Phenols (Salicylic Acids)
Aminophenol

II

IMPORTANCE OF PRESENCE AND NUMBER OF FREE PHENOLIC HYDROXYL-GROUPS:

Benzenes and DN-Benzenes
DN-Chlorobenzene
DN-Toluene
DN-Anisole
DN-Phenetole

III

INTRODUCTION OF SECOND RING-SYSTEM:

DN-Naphthol
DN-6-cyclo-hexyl-phenol

IV

INTRODUCTION OF ADDITIONAL NITRO-GROUP OR HALOGENS:

Picric Acid
2,4-DN-Chlorophenols

V

IMPORTANCE OF METHYL- AND OTHER ALKYL-GROUPS:

DN-Cresol
DN-Thymol
DN-tertiary butyl-phenol
DN-Mesitylene

VI

OTHER CYCLIC COMPOUNDS:

Naphthalene
Nitro-Cinnamic Acid

SUMMARY OF TABLE 2

Table 2 illustrates that any omission or substitution of any of the two nitro-groups by either halogens or carboxyl-groups abolishes cataract-producing activity with the exception of 2,6-dibromo, 4-nitrophenol; that is, of a compound where one nitro-group in paraposition is maintained in addition to two halogens in ortho-position to the phenolic hydroxyl-group. It is of interest that 2,6-dinitro-4-chlorophenol—that is, a compound with two nitro-groups in ortho-position and one halogen in para-position—seems to be less active, although the higher general toxicity makes it difficult to draw very definite conclusions.

Shifting of the second nitro-group from para-position into ortho-position in 2,6-dinitrophenol reduces activity considerably.

It is obvious that the optimal situation is the presence of two nitro-groups, one in ortho-, the other in para-position, and that the presence of one nitro-group in para-position is of greater importance than the one in ortho-position.

SUMMARY OF TABLE 3

Omission or substitution of the phenolic hydroxyl-group by a halogen or methyl-group abolishes cataract-producing activity. The presence of the phenolic hydroxyl group is an absolute necessity. The activity of the anisole- and phenetole-compounds is most likely to be explained by an hydrolysis of the ester with liberation of the free phenol in the body; the somewhat delayed onset of cataract after administration of these compounds is in agreement with this interpretation.

SUMMARY OF TABLES 4 AND 5

Introduction of a second ring system into the molecule interferes with cataract-producing activity.

tional methyl-groups and more complex alkyl-side-chains interferes with the cataract-producing activity.

SUMMARY OF TABLES 7 AND 8

The absence of any cataract-producing activity of naphthalene in acute experiments in the chick is of interest and will

be referred to again in the discussion on the specificity of the effects of dinitrophenol.

Table 8 summarizes the approximate relative cataract-producing activities of various compounds of the previously discussed groups.

DISCUSSION

1. SPECIFICITY

The absence of any cataract-producing effect of naphthalene in very high concentrations in these acute experiments and the loss of activity with even much slighter modifications in the molecule indicates that the cataract due to D.N.P. is a very specific phenomenon. Therefore, it appears very doubtful that the pathogenesis of cataracts, both clinical and experimental, reported in poisoning with various cyclic compounds has much in common with the mechanisms primarily concerned in D.N.P. cataract.

2. RELATION TO OTHER BIOLOGIC EFFECTS

Various nitro- and other substituted phenols, notably halogen-phenols, have

TABLE 8

been extensively studied by Krah1 and Clowes^{8, 8a} in their effect on mitosis and metabolism in the eggs of some marine animals. The interference of halogen substitution and ring-system substitutions with cataract-producing activity is in strong contrast to these effects on marine eggs where both mitosis and respiration are similarly affected by nitro-phenols and by halogen- and some double-ring-phenols. This lack of correlation again underlines the high specificity we have to assume for the mechanisms involved in D.N.P. cataract.

The drop of body temperature found in chicks which had been poisoned with cataract-producing nitro-phenols has also been found with compounds which did not produce cataract and may be ascribed to other unrelated toxic effects of these compounds. Moreover, adult chickens did not show a drop in temperature, and it can, thus, be excluded that the cataract is a cold-cataract or otherwise closely or directly related to the body temperature changes.

A fairly good correlation was found between the cataract-producing activity and the metabolic effects on the whole animal of various compounds as tested by the basal metabolism. With at least two compounds, 2,6-D.N.P. and 2-chloro, 4,6-D.N.P., no increased metabolic rate was found in chicks in spite of the production of cataracts. It has to be admitted, however, that with these compounds the onset of cataract was delayed and that the difference as compared with other compounds may turn out to be only a question of dosage, if this could be tested without entering the ranges of general toxicity. At any rate, these two exceptions are not sufficient to justify the conclusion that the increased oxygen uptake does not have some relation to the cataract. It is quite conceivable that an increased oxygen uptake of the tissue is not

the cause of the cataract, but rather a corollary, secondary effect of some primary metabolic disturbance and that a further set of unknown factors determines whether the oxygen uptake is increased in the tissue with no production of cataract, or cataract is produced without an increase in oxygen uptake, or whether both effects take place. It is of some interest in this connection that Field II, Tainter, Martin, and Belding⁹ found an increased respiration in rabbits' lenses with certain concentrations of D.N.P., while it is known that this species is not susceptible to D.N.P. cataract.

The notion that the increased respiration is not the cause and is only indirectly connected with the cataract mechanism can easily be reconciled with a recent viewpoint held by biochemists on the mechanism of action of D.N.P. in tissue metabolism. It has been found that D.N.P. interferes vigorously with the phosphorylative processes in microorganisms;¹⁰ the viewpoint based on these experiments is that increased respiration is only secondary to these disturbances in phosphorylative mechanisms and that, with this increased oxidation, energy is wasted and sidetracked from storage and utilization in high-energy phosphates which are connected with some specific tissue functions.¹¹ Experiments designed to test phosphorylative mechanisms in chick lenses with these various compounds and to correlate them to their respective cataract-producing activities would seem to be a promising experimental approach.

SUMMARY

1. Acute reversible cataracts can be produced in chicks and chickens of any age within 1 to 1½ hours after application by stomach tube or by intramuscular injection of small amounts of 2,4-dinitrophenol in peanut oil. The threshold

dose is about 0.06 millimol per kg. body-weight.

2. In ordinary feeding experiments spontaneous recovery takes place; that is, the lenses clear again, in spite of continued presence of the drug in the diet.

3. Experiments to produce D.N.P. cataract in vitro have failed.

4. Thirty-seven chemically more or less closely related compounds have been tested for their cataract-producing activities. Of these, only eight produced cataracts in vivo within from 1 to 5 hours after administration, 3,5-dinitro-o-cresol (4,6-dinitro-o-cresol in another nomenclature) being the most efficient one with an activity about five fold that of D.N.P. itself. The most outstanding properties favoring cataract-producing activity are

the presence of a phenolic hydroxyl-group, and of at least one nitro-group, preferably in para-position, while the addition of a second ring abolishes activity.

5. The cataract is not a cold-cataract nor an osmotic cataract due to dehydration.

6. A fairly close, but not absolute, correlation exists between the cataract-producing properties of these compounds and their ability to raise the basal metabolism of the animal. The possibility is discussed that an increased tissue respiration is only a corollary effect, and that the cataract is more directly related to other metabolic effects of these nitro-compounds and not caused by the increased respiration.

DISCUSSION

DR. CLYDE A. CLAPP (Baltimore, Maryland): I should like to ask Dr. Buschke if he considers a reversible opacity in the lens as a true cataract or simply an opacity in the lens?

DR. WILHELM BUSCHKE (New York): Well, I think that depends on the definition of the word "cataract." From a patho-physiologic standpoint, I think the essential thing is the change which takes place in the optical properties of the lens. As long as we don't know more about the pathogenesis of cataracts we had best stick to a definition based on this criterion, but for our purpose it doesn't matter much whether we call it "cataract" or "lens opacity."

Now, the interesting point in this type of lens opacity is that in various species it behaves differently. In human beings, it is not reversible; while in the animal it is. This raises the question whether this experimental cataract can be considered as analogous to the clinical cataract produced with this compound in human beings. I believe, however, it would be very far-fetched to assume that lens opacities produced by compounds of this type, both clinically and in experimental animals, would have nothing to do with each other, even if they follow a different course in different species.

DR. CLAPP: I should also like to ask Dr. Buschke what the difference is between a transparent protein and one which is opaque—for instance, what is the difference between clear proteins and precipitated proteins? Is it a chemical change or is it a physical change, with the rearrangement of the molecules or the atoms.

DR. VERHOEFF (Boston, Massachusetts): Does that have anything to do with this particular paper?

DR. CLAPP: I should think that any change in opacity is part of any change in the lens itself.

DR. VERHOEFF: Well, if Dr. Buschke would like to answer it, all right.

DR. BUSCHKE: I should be very happy if I could answer this question in relation to the lens because then, I think, the cataract problem would be solved; but I do not claim to have solved this problem.

DR. VERHOEFF: Most of us here are clinicians and I think we always try to apply everything clinically as far as possible. Perhaps that is not the correct attitude, but we all have it. I should like Dr. Buschke to tell us whether he has attempted to correlate his experimental work with the dinitrophenol cataract of human beings; for instance, does he think that every human subject would develop this cataract if the dose were sufficient? Or are certain individuals susceptible and others not? I don't know whether or not Dr. Buschke's experiments could be expected to cover that.

DR. BUSCHKE (closing): I think this is a very interesting and intriguing question. Of course, my experiments do not provide any direct answer to this question. However, according to Horner only a very small percentage of human beings, who have ingested the drug, do get cataract, and the occurrence of the cataract in human beings is correlated neither to the amount of drug nor to the period over which it has been taken. It appears, both on the basis of clinical observations and by virtue of the fact that—in contrast to human beings—these compounds produce lens opacities with about 100 percent regularity in some other species, that a genetic predisposition plays an important role in the susceptibility to this cataract.

VIRUS STUDIES IN LYMPHOMATOID DISEASES OF THE OCULAR ADNEXA

ALSON E. BRALEY, M.D., AND ROSE C. ALEXANDER, M.S.
New York

INTRODUCTION

The possibility of viruses causing neoplasms is not a new concept. Borrel¹ suggested that cancer was the result of virus infections. Since then investigators in France and elsewhere have found neoplasms containing viruses. The hypothesis of the virus etiology of cancer has had a rather stormy course, and the majority of cancer-research groups refuse to consider it as a possibility. Duran-Reynalds and Shrigley² have compiled a large bibliography on the virus approach to the cancer problem.

Several general and ophthalmic pathologists have considered the possibility of some inflammatory diseases becoming neoplastic; this has been particularly true in the syndrome known as pseudotumor of the orbit. Biopsies of this peculiar orbital disease histologically show chronic inflammatory tissue. Similarly there has always been considerable confusion among these inflammatory tumors, lymphomas, and malignant exophthalmos associated with hyperthyroidism.

Birch-Hirschfeld³ classified most of the types of orbital tumors, particularly pseudotumors. He classified the pseudotumors of the orbit as follows: (a) exophthalmos which regresses spontaneously, (b) exophthalmos associated with a definite orbital tumor that is relieved by removal of the tumor, and (c) exophthalmos which persists. Occasionally these

pseudotumors of the orbit continue to extend and eventually a diagnosis of malignant lymphoma is made; although numerous associated lymph nodes may develop over the rest of the body, most of these individuals do not follow the usual course of a malignant lymphoma.

The present investigation was undertaken in order to determine the etiology of this particular type of malignant exophthalmos.

CASE REPORT

HISTORY

J. W. B. was first examined by numerous physicians in Glasgow, Scotland, in August, 1938, because of edema of the lids and conjunctivitis. Behind the upper lid was a palpable mass, and there was some exophthalmos of both eyes. The upward rotation of the right eye was limited; diplopia was present in this field and at times in the primary position. He gave a history that the swelling in the upper lids began insidiously in May, 1937. At that time it was thought that the swelling was allergic.

In October, 1938, two portions of the growth were excised by Professor Ballantyne. Sections of the tumor suggested a probable giant follicular lymphoma. X-ray studies of the chest was normal, and the vision at that time was 6/3 in each eye. The patient was given a course of X-ray therapy during which time his exophthalmos increased so that approximately six months later it measured 25 mm. in each eye.

VISUAL EXAMINATIONS

In May, 1939, he developed marked chemosis of the bulbar conjunctiva. The

vision was reduced to 6/9 in each eye. The differential blood count showed a marked eosinophilia, there being 14-percent eosinophiles with 61-percent neutrophiles; the lymphocytes were only 18 percent. A biopsy of the conjunctival tissue was performed, and the diagnosis of possible lymphocytoma was made. There were large numbers of eosinophiles present in the conjunctival tissue. The patient was

in the left eye. The exophthalmos was still marked. In November, 1942, a right frontal osteoplastic craniotomy was performed and the roof of the orbit was removed. Considerable orbital tissue was excised. Microscopic examination of the tissue showed a tumor of the myeloma group, probably plasmocytoma. However, the cells varied in type, and the muscles and connective tissue contained many eo-

Fig. 1 (Braley and Alexander). These pictures of J. W. B. show the progress of the disease. The first was taken in September, 1938; the second in May, 1940; and the third in September, 1945.

given another course of X-ray therapy but with little improvement; the exophthalmos continued and by June, 1939, it had increased so that the apex of the cornea measured 33 mm. in each eye from the lateral rim of the orbit.

He was again seen in March, 1940, and the eyes were more divergent; the interpupillary distance measured 71 mm.; the vision was reduced to 6/13 in the right eye and 6/36 in the left eye. The exophthalmometer reading was 31 mm. in the right eye and 36 mm. in the left eye. He was given repeated X-ray treatments, and the condition seemed to relapse so that by January 1, 1942, his vision had improved to 6/6 in each eye and the exophthalmos had decreased. However, by February, 1942, there was loss of vision, and the patient had many areas of degeneration in the fundi; it was noted that he also was developing cataracts.

By September, 1942, the vision was reduced to 3/60 in the right eye and 6/24

sinophiles and plasma cells. He was seen again a month later with marked ulceration of both corneas. The exophthalmos seemed to be greater than before the operation. By January, 1943, the eosinophilia had increased to 44 percent and the neutrophilic polys were 47 percent.

The patient was not seen for the next 2½ years but the proptosis continued and he developed bilateral cataracts. He was next seen in July, 1946, by Dr. A. B. Reese, whose examination revealed an extreme exophthalmos of both eyes which could not be measured with the exophthalmometer. Both eyes were fixed, the right eye turning down and out. There was edema and protusion of the bulbar conjunctiva of the lower lids with hyperkeratosis. In both orbits, firm nodular tissue was palpable through both the upper and lower lids. There were bilateral cataracts, and the right cornea showed extensive vascularization below, apparently due to exposure. There were tremendous tortu-

ous blood vessels in the lower fornix of the right eye. There were large lymph nodes in both sides of the neck extending into the cervical region.

It is interesting to note that on only three occasions was there any remission in the exophthalmos. This was during and following a severe bronchial pneumonia, for a short time after the craniotomy, and after an attack of pleurisy. On each occasion the exophthalmos returned.

PHYSICAL EXAMINATION

The patient's blood pressure was 126/90 mm. Hg; the physical examination except for the head, neck, and eyes was essentially negative. There was an advanced exophthalmos with marked edema of the lids. There were numerous lymph nodes in the submaxillary region and many lymph nodes in the anterior and posterior cervical triangle. The parotids also appeared to be swollen, but there was no preauricular lymph node palpable.

The skin test with tuberculin was slightly positive in 1:100,000 dilution; however, when this test was repeated with 1:10,000 dilution it was entirely negative. The Frei test was negative, the brucella-lymph node test was positive, and the blood Kline was negative. The blood count showed 11.6 gm. of hemoglobin, 3,850,000 erythrocytes, and 8,400 leukocytes. The sedimentation rate was elevated by 101 mm. in one-half hour and 127 mm. in one hour. There was 45-percent neutrophils, 20-percent eosinophils and 34-percent small and large lymphocytes. The metabolic rate was +15, but this reading was not reliable. There was diffuse clouding in the X-ray pictures of the sinuses. Repeated blood counts showed a definite eosinophilia ranging between 20 percent and 24 percent. X-ray studies of the chest showed definitely enlarged hilar lymph nodes; and the blood agglutination for

brucella was positive up to 1:320. Blood cholesterol was normal and the A/G ratio was 0.2. There were no changes in the long bones or in the joints in the hands. Fasting blood sugar was 83 mg. percent and the blood-sugar curve was normal. The cephalin flocculation was negative. Serum phosphatase was 1.4 Bodansky units. The urea-nitrogen was 16 mg. percent.

A biopsy of the left submaxillary gland and several lymph nodes was done since the patient did not wish to have his orbits reexamined. There was considerable confusion in the diagnosis of the tumor. It was considered a giant follicular lymphoma by the majority of pathologists, but Dr. A. P. Stout thought the tissue inflammatory and not neoplastic.

PATHOLOGY OF CLINICAL DISEASE

A microscopic slide made from the original biopsy of the orbit was available for examination. The section shows an elongated piece of tissue on one side of which a small bit of glandular material is seen. The gland appears to be part of the lacrimal or accessory lacrimal gland. The tissue is composed mostly of dense strands of connective tissue. Interposed between these strands are collections of lymphocytes. The connective tissue is also lightly infiltrated with lymphocytes. The masses of lymphoid tissues are in general similar; they are composed of small and large lymphocytes at the periphery of the masses and, near the center, the lymphocytes become paler and suggest a germinal center. These central areas are composed of pale, blue-staining cells in which an occasional mitotic figure is present. There is also an occasional eosinophilic cell in these masses. The tumor has the general appearance of a giant follicular lymphoma.

The lymph nodes and submaxillary gland from which the animal inoculations

were made were also available for histologic examination. The lymph node has lost most of its normal markings. The sinusoids are densely infiltrated and there are no definite lymph follicles with germinal centers seen. The entire lymph node is generally infiltrated with lymphocytes. The normal architecture of the hilar area is obliterated because of the lymphocytes.

Fig. 2 (Braley and Alexander). Experimental studies showing the marked infiltration with lymphocytes.

Most of these lymphocytes are mature; there are a few cells that simulate lymphoblasts scattered in the lymph node and an occasional plasma cell. There are also a few plasma cytoids and Russell bodies present. Under the oil-emersion lens, most of the larger cells appear to be endothelial cells from the lymph sinusoids, and some of these cells appear to be degenerated. Some of the cells are multinucleated simulating Dorothy-Reed cells. An occasional eosinophile is present. The submaxillary gland is densely infiltrated with lymphocytes so that the glandular tissue is spread apart by the collections of lymphoid elements. It is composed more of lymphoid tissue than of normal glandular tissue. The lymphoid tissue here is likewise composed largely of adult lymphocytes. There may be a few more eosinophiles present in the submaxillary gland than in the lymph node. An occasional

plasma cell and a few plasma cytoids are present. Some of the cells which appear to be large lymphocytes show clear spaces in the nucleus which could represent nuclear inclusions, but these are indefinite. Some of the collections of lymphocytes appear to have germinal centers.

METHODS OF STUDY

A large lymph node and several pieces of the submaxillary gland were available for study. The tissue was divided into six parts. One part of each section was studied histologically; some of the tissue was placed in the deep freeze and other material was macerated in balanced salt solution. Two types of tissue culture were inoculated with this material. One type consisted of serum ultrafiltrate, balanced salt solution, and finely-divided embryo mouse brain, similar to the procedure followed by Simms and Sanders⁴ for propagation of lymphogranuloma virus. The other type of tissue culture was similar except that 17-percent sterile horse serum was substituted for the serum ultrafiltrate. This latter type of tissue culture maintained a more normal pH without adjustment with carbon dioxide as is required with serum ultrafiltrate. All of the inoculated tissue cultures were carried at incubator temperature (37°C.).

These tissue cultures were subinoculated at varying intervals of from 4 to 6 days, then inoculated intracerebrally and intraperitoneally into mice. The original tissue cultures were reinoculated into fresh tissue cultures when the mice were inoculated. The inoculated mice were followed for periods of from 4 to 6 weeks before they were discarded. As the tissue cultures increased in number, each series was inoculated intracerebrally and intraperitoneally into mice. After five consecutive passages through tissue cultures, two of the six mice inoculated

showed signs of encephalitis. Their brains were removed and passed in tissue cultures and other mice. Subsequently a potent agent was obtained, and this procedure of inoculation from tissue culture to mice has been carried on for 28 consecutive passages. During this process, the potency of the virus gradually increased so that it was necessary to make serial dilutions of the tissue culture before the test mice could be inoculated. The tissue-culture potency of the virus was raised to 10^{-6} when tested by serial dilutions intracerebrally in mice. The highest potency of the virus obtained in tissue culture was after four days at incubator temperature.

At the same time that the original tissue cultures were inoculated, the glandular tissue was also macerated in balanced salt solution and inoculated intracerebrally into two guinea pigs, two rabbits, and six mice. The first rabbit developed paralysis of the hind legs 22 days after inoculation; the rabbit lost weight and became lethargic. When it was apparent that the rabbit was ill with an encephalitis, it was killed and the brain removed. The entire brain was stored at -50°C . The second rabbit developed similar symptoms 35 days after inoculation; this brain was also removed and stored at -50°C . The rabbit brain was inoculated into tissue culture, intracerebrally and intraperitoneally into six mice, and intracerebrally into other rabbits. After eight days two of the six mice were dead. The first rabbit inoculated developed encephalitis in 10 days and the second in 12 days.

Of the two guinea pigs inoculated from the original material, the first developed symptoms in 23 days and the second in 32 days. They showed signs similar to the rabbit in that they became lethargic and developed slight paralysis of the hind legs. Their brains were removed and inoculated into other guinea pigs. When it was apparent that an agent was present

which would produce an encephalitis in rabbits and guinea pigs, it was decided to inoculate some of the original tissue which had been kept at -50°C . This material was thus inoculated intracerebrally into guinea pigs and although it produced an encephalitis, the incubation period was prolonged to 42 days and 45

Fig. 3 (Braley and Alexander). Pathology of material for investigation. This shows the marked replacement of the submaxillary gland by lymphocytes.

days, respectively. Since this material appeared to be less virulent than the fresh tissue and was less virulent than the material already obtained in rabbit and mouse brain, it was decided to discontinue these studies.

The second intracerebral guinea-pig inoculation of brain suspension shortened the incubation period. The incubation period was decreased to 14 and 17 days, respectively. The intracerebral transmission into other guinea pigs was continued and again the incubation period was re-

duced; however, one guinea pig was encountered which did not develop symptoms until three months after inoculation. Four consecutive guinea-pig passages were done. Some of the guinea-pig brain was also used to inoculate tissue culture and eventually produced an encephalitis in mice.

Investigation was carried on for the most part with rabbits and mice, utilizing

Fig. 4 (Braley and Alexander). Rabbit brain after inoculation with virus shows infiltration with lymphocytes.

tissue culture as an intermediate media to increase the potency of the virus. Six serial passages were carried out in rabbits. All the rabbits were inoculated in a similar manner. The inoculum consisted of a 1:10-dilution of rabbit brain suspension from the previous animal. This material was ground in a ball mill and sufficient balanced salt solution added to make the dilution. Adult rabbits were partially anesthetized with either inhalation ether or nembital intraperitoneally, and a small

trephine was made through the skull with a short sharp punch. The hair over the skull was shaved prior to the punch, and the entire area painted with iodine. A needle was then inserted into the brain and from 0.2 cc. to 0.5 cc. of this inoculum injected. Although the incubation period of the original material was approximately three weeks, the second rabbit developed symptoms in two weeks. In the third rabbit passage, the incubation period was reduced to one week, and from then on the incubation period did not seem to shorten materially. At each passage some of the rabbit brain was removed for mice- and tissue-culture inoculations. After the second passage in rabbits, 2 of 6 mice died from the direct rabbit-brain inoculation. The tissue culture from this brain was assayed in mice, but its potency was not increased. With each continual passage in rabbits, however, more mice in each series died from the intracerebral inoculation, so that after the fourth passage in rabbits, intracerebral inoculation of the rabbit-brain material produced encephalitis in all of six mice inoculated. After the fourth passage in rabbits, the rabbit-brain material was transmitted intracerebrally to guinea-pig brain and found to be highly potent, the incubation period being reduced to five days. In order to increase the potency of the virus one of the tissue cultures from the fifth passage in rabbits was passed at 5-day intervals. The potency in tissue culture gradually increased so that, when assayed in mice, it killed all of the mice inoculated.

During the early part of the experiments, mice were inoculated both intracerebrally and intraperitoneally. After the fifth passage in rabbit brain, only the intracerebral mouse inoculations were necessary to kill the mice. Because of the expense involved in continual passage in rabbits, we felt that six passages in rabbits were all that were necessary, since we

had the virus not only in rabbits but also in mice, guinea pigs, and tissue culture. By transferring the rabbit brain and mouse brain into tissue culture and back into mice, a very potent virus was obtained. In tissue culture a potency of 10^{-6} was present; in mice this was increased to 10^{-7} . Each of the isolations produced an identical virus.

NEUTRALIZATION TESTS

Gordon,⁵ in 1933, reported a successful transmission of Hodgkin's disease in rabbits. Ground Hodgkin's lymph nodes suspended in saline and injected intracerebrally in rabbits produced an encephalitis from which the rabbits eventually died. The symptoms that were obtained by Gordon were similar to those we found in rabbits. Gordon was unable to transmit the rabbit encephalitis to other rabbits. It was later shown by Turner, Jackson, and Parker⁶ and again by McNaught⁷ that intracerebral inoculation of eosinophiles would produce the same encephalitis in rabbits. Our agent, however, could be transmitted in rabbits, guinea pigs, and tissue culture.

When an agent is present in the body it usually stimulates the formation of antibodies. Therefore, one of the best methods of determining if a virus was obtained from an individual is to search for substances which will neutralize the virus. There are several methods of determining antibodies, but the easiest is to determine their presence in blood serum. It has been shown that after a disease has been present for a varying length of time antibodies are produced. One method of determining their presence is by mixing the virus with the blood serum and then testing for the presence of the virus. In order to arrive at a definite figure, it is necessary to determine the potency of the virus by serial dilutions. These dilutions are usually made in powers of 10. Each

dilution is made so that when 0.02 cc. is injected intracerebrally in mice the actual dosage in mice is 1:10, 1:100, 1:1,000, 1:10,000, and so forth. These dilutions are, therefore, made by logarithmic power. The serial dilutions are then called 10^{-1} , 10^{-2} , 10^{-3} , and so forth, until a dilution is reached where the animals inoculated remain alive after inoculation. If a definite amount of blood serum is added to each of these dilutions so that subsequent dilution is the same as the control to which no serum is added, this can be used as a test to determine the presence or absence of neutralizing antibodies in the serum and the number of neutralizing antibodies when compared to the control. To determine the presence of antibodies each of the dilutions from 10^{-1} to 10^{-6} were injected intracerebrally into three mice, so that for each test 18 mice were used. If the serum completely neutralized the virus, then all the injected mice remained alive while the control mice died. If the serum partially neutralized the virus, then those with the lower dilutions of the serum-virus mixture died while those with the higher dilutions remained alive. This would then indicate a certain degree of antibodies.

Antisera were obtained which would neutralize the viruses of herpes simplex and epidemic keratoconjunctivitis. Normal rabbit serum, normal mouse serum, and several normal patients' sera were also analyzed; blood serum from the patient from whom the tissue had originally been obtained was tested. None of the known sera neutralized the virus; however, the patient's serum neutralized the virus in all dilutions up to 10^{-1} . With normal human sera, all mice were dead in dilutions up to 10^{-6} . Normal rabbit and mouse serum possessed no antibodies to the virus, and only one other patient was found who had any evidence of neutralizing substances in the serum.

Since the amount of serum needed from the patient in conducting neutralization tests was great, we thought it advisable to try to develop an antiserum in animals. Therefore, following a hyperimmunizing procedure, we injected rabbits intraperitoneally and intravenously with small amounts of the virus. Gradually increasing the amount of virus injected gives rise to high antibody titre in rabbits; the rabbit serum can then be used in neutralization tests. After intravenous inoculation with the virus, the rabbits gradually began to lose weight and, although we gave small quantities of the virus, we were unable to demonstrate antibodies in the majority of rabbits. During the intravenous inoculation, blood studies on the rabbits showed a marked increase in the number of lymphocytes. There was only a slight increase in blood count of the rabbits, but the lymphocytic count was as high as 90 percent. This was associated with a slight increase in the lymph nodes throughout the body, particularly those in the peripheral lymphatic system. X-ray studies of the chest and postmortem examination of the mediastinum failed to demonstrate a lymphadenopathy. One rabbit was finally obtained whose serum showed neutralizing antibodies. The antibodies that were present, however, only partially neutralized the virus. When rabbits were inoculated intracerebrally with small amounts of the virus so that the incubation period was prolonged to about three weeks, if they were bled during the first few days of their illness they showed some neutralizing antibodies. Usually these neutralizing antibodies did not develop above 10^{-4} .

In all the neutralization studies we have found only two patients who possess antibodies to the virus. One was the patient from whom we obtained the original material, and the second was a woman who had a peculiar lymphoma in the conjunc-

tiva associated with numerous lymph nodes in the neck. Material was obtained from this patient for study but thus far no definite findings can be presented.

An attempt has been made to obtain serum from other types of lymphatic disease. Blood serum was obtained from four patients suffering from Hodgkin's disease. These patients were in various stages of Hodgkin's disease, and we feel that they should have had neutralizing antibodies if our virus was related to Hodgkin's. None of the patients' sera had any evidence of circulating antibodies to the virus.

FILTRATION EXPERIMENTS

Insufficient data has been collected on filtration to indicate the size of the virus, but enough has been done to show that the virus is small and passes most filters readily. The Seitz absorption-type filter passes the virus in low dilutions. Most of the gradacoll filters we have at hand pass the virus; it appears to pass the gradacoll filter with an average pore size of 93 millimicrons. No high-speed centrifugation experiments have as yet been done.

ATTEMPTS TO REPRODUCE THE CLINICAL DISEASE

When the material is injected intravenously in rabbits, there is a gradual weight loss and in some of the rabbits there is a gradual lymphadenopathy. With the intravenous injection, there appears to be a marked increase in the number of white blood elements. In some instances actually there is a decrease in the white elements from 6,000 to 5,000. The normal white count in a rabbit varies from 3,000 to 7,000. After intravenous inoculation with the virus, the relative number of lymphocytes increases up to 90 percent. There are two possible explanations; either the virus destroys the leukocytic group leaving only the lymphocytic cells,

or the lymphocytes are increased at the expense of the leukocytic cells. The differential counts in rabbits range from 80 to 90-percent lymphocytes, while in normal rabbits the lymphocytic count is rarely over 50 percent. Most of the differential counts in normal rabbits show about 50-percent polymorphonuclear leukocytes and from 40 to 50-percent lymphocytes. In most instances after intravenous inoculation, there is some increase in the size of the lymph nodes. This is particularly pronounced in some of the rabbits; however, this finding seems to be inconsistent, and by intravenous inoculation it is not always possible to produce lymphadenopathy or consistent blood changes.

Single intraperitoneal inoculation into rabbits produces little change except on postmortem examination where there is an increase in the number and size of the lymph nodes. Retrobulbar inoculation of tissue culture containing the virus produces an exophthalmos which persists over a long period of time but gradually seems to decrease. The rabbits given retrobulbar inoculation, however, developed signs of an encephalitis and eventually died. They likewise showed enlargement of the spleen and the liver. The rabbits with the retrobulbar injection developed some neutralizing antibodies to the virus before death. To determine whether the virus produced the exophthalmos and eventual death of the rabbits, one rabbit was inoculated intraorbitally with normal tissue culture. Another rabbit was inoculated with tissue culture in which the virus had been grown for four days. Part of this culture was inoculated into the orbit and another part heated to 60°C. for one hour. This heated virus was also injected into the orbit. Neither of the latter two rabbits showed any symptoms of exophthalmos nor did they develop antibodies to the virus.

PATHOLOGY OF THE EXPERIMENTAL DISEASE

The liver, lungs, spleen, and lymph nodes were available for microscopic examination from rabbits which had been given the virus intravenously. The lymph nodes are enlarged but still show reasonably normal architecture. The sinusoids and the hilar region of the lymph nodes show some increase in the lymphocytic infiltration. There are quite a number of mitotic figures present in the lymph nodes, especially in the germinal centers. In some of the lymph nodes there are a few eosinophiles. The lungs show slight lymphocytic infiltration in the alveolar wall, but most of the lymphocytes are perivascular. The most striking change in the rabbit is in the liver where there is dense lymphocytic infiltration around the blood vessels at the periphery of the liver lobules. There are also lymphocytic infiltrations around the biliary capillaries. The spleen shows some increase in pigmentation and some evidence of increase in the amount of cellular debris but is otherwise normal.

The histologic examination of the rabbit brain which had been inoculated directly with the virus shows the most striking change. The arachnoid is densely infiltrated with lymphocytes. In spite of the fact that there is considerable thickening of the arachnoid and dense infiltration with lymphocytes, no polys are present. There is also considerable cellular debris in the arachnoid, and some of this debris is being phagocytized by large mononuclears. The brain substance in some areas is densely infiltrated with lymphocytes, particularly in the basal portions around the brain stem. Sections of the sixth passage of rabbit brain shows the most advanced pathologic processes. There is a moderate amount of death of brain cells, particularly the large ganglion cells. The cells are shrunk away from

the brain tissue and show some pyknosis. A few show small astrocytes around them.

Guinea pigs inoculated intraperitoneally showed some increase in the size of the lymph nodes. Histologically these lymph nodes show more changes than those found in the rabbit. The entire lymph node is densely infiltrated with lymphocytes, and the normal markings appear to be compressed. The entire area is densely infiltrated and some of the larger cells appear to be lymphoblasts. There is an occasional eosinophile in the sections. The spleen appears to be normal. The sections of the liver also show perivascular infiltration of lymphocytes at the periphery of the lobules.

Sections of mouse brain inoculated directly with the virus show similar pathologic processes to those seen in the rabbit. The lymphocytic infiltration of the arachnoid and pia is marked, but there is considerably more infiltration of the brain substance. This is particularly true around the ventricular spaces.

The pathologic condition of the animals studied demonstrates that the virus when inoculated into animals gives rise to a generalized lymphocytic infiltration no matter in what manner the virus is inoculated.

DISCUSSION OF THE EXPERIMENTAL DATA

Several pieces of tissue obtained from the submaxillary gland and adjacent lymph nodes were inoculated into tissue culture, mice, guinea pigs, and rabbits. The tissue culture was passed serially and eventually became infectious for mice. The intracerebrally inoculated rabbits developed an encephalitis, and their brains contained an agent which could be transmitted from one rabbit to another. With each passage the incubation period was decreased and the severity of the encephalitis increased. Six consecutive

passages were accomplished in rabbits. The rabbit brain inoculated into tissue culture became infectious for mice. The original guinea pigs inoculated also developed encephalitis and the agent was successfully transmitted in guinea pigs three times. The substance present in guinea-pig brain, after passage in tissue culture, became infectious for mice.

The infectious agent when grown in tissue culture was transmitted to mice, rabbits, and to a lesser degree to guinea pigs. The potency of the agent in passage in mice had been increased to 10^{-7} dilution. The potency in tissue culture when tested in mice had been increased to 10^{-6} . When the virus was grown in tissue culture, the optimum requirement for highest titre was four days at 37°C . There was no visible change in the appearance of the tissue culture when the titre of the infectious agent was highest. We, therefore, obtained from the original tissue by three different methods an agent which produced identical symptoms in each test animal when passed from one to another.

Whenever an apparently new virus is discovered by animal inoculation, there is always a possibility that a latent virus was stimulated in the animal inoculated. There are several methods of determining whether the virus found was present in the animal inoculated. Most viruses have a definite host range. This is particularly true of Theiler's virus, which is usually picked up in the mouse and is noninfectious for rabbits and only slightly infectious for guinea pigs. The mice inoculated directly with this material did not develop symptoms. If the virus encountered had been Theiler's, herpes, or some other virus, the inoculation of mice would have immediately produced symptoms.

There was no evidence of neutralizing antibodies in normal rabbit blood, normal mouse blood, or normal guinea pig blood. Normal human serum also failed to neu-

tralize the virus. Only two human sera have been found that possess neutralizing antibodies to the virus—the patient from whom the original tissue was obtained and another individual who is suffering from a peculiar type of lymphoid disease. Our disease is probably not related to Hodgkin's or similar lymphoma since none of the serum tested from patients with these diseases possessed neutralizing antibodies.

The virus when inoculated intracerebrally into animals gave rise to an encephalitis in which the cellular reaction was entirely lymphocytic. When inoculated intraperitoneally and intravenously, there was an increase in the lymphocytic elements with a marked decrease in the leukocytic cells. The virus may destroy the leukocytes rather than increase the lymphocytes since there was no appreciable increase in the number of white blood elements present.

The virus could be one of the causes of pseudotumor of the orbit. It is known that in pseudotumor of the orbit many patients develop exophthalmos which persists for a long period of time but may spontaneously disappear with or without treatment. Some pseudotumors of the orbit persist for long periods of time and develop into a definite tumor with persistent exophthalmos. When these are removed, results are usually good. The third type of pseudotumor is, in some respects, similar to that of the patient presented here in that the tumor increases in spite of treatment and is histologically indistinguishable from some of the lymphomas. Whether the virus found in this patient has any relationship to the usual lymphoma has not been determined.

From the blood-neutralization experiments, it would appear that the virus has no relationship to Hodgkin's disease. Insufficient data are at hand to determine this point at the present time. It may be that the virus can give rise to several types of lesions which vary from entirely benign to potentially malignantlike tumors so that when present in the lymphoid tissue it may give rise to a quasi-lymphoma.

An attempt is being made to isolate a virus from the only other patient who had neutralizing antibodies to the virus. The amount of material obtained from this patient was relatively small, and at the present time it is doubtful that we will recover a virus from this patient.

CONCLUSIONS

1. A preliminary report of a new virus is presented.

2. This virus was obtained from lymph nodes and submaxillary gland of a patient suffering from a type of malignant exophthalmos.

3. The virus produces an encephalitis in rabbits, guinea pigs, and mice and grows well in tissue culture.

4. The cellular response to the virus in animals is predominantly lymphocytic.

5. The virus is small in size and is submicroscopic.

6. The virus is neutralized by blood serum from the patient.

7. Normal human serum and the blood serum of most laboratory animals contain no neutralizing antibodies.

8. The virus has not been identified in any known classification.

635 West 165th Street (32).

DISCUSSION

DR. F. H. VERHOEFF (Boston, Massachusetts): I would like to ask what happened to the patient. What was the further course. Did he recover?

DR. ALSON E. BRALEY (New York): He was given X-ray treatments. When last heard from, his progress was satisfactory. Although he thought he was slightly improved, he had no vision in either eye and there was marked exophthalmos. He had been given a large number of X-ray treatments.

DR. VERHOEFF: Your explanation is that the case is one of an atypical pseudo-tumor.

DR. BRALEY: Yes, sir.

DR. VERHOEFF: This might simply be one of the more severe cases. Some of these patients have much more resistance.

I also wanted to point out that at the time you first saw this patient there was a tremendous lymphoma and granuloma, and that you found what I think is a characteristic thing—a little lymphoid follicle, with profuse obliteration of the blood vessels.

DR. PARKER HEATH (Boston, Massa-

chusetts): I would like to ask a question. Do you classify this man as a case of real Brill-Shimmer's disease?

DR. BRALEY: No, sir, I don't know how we should classify him. I have looked over all his slides from 1938 to the present time, and there is a tremendous variation in the microscopic appearance of the tumor. The first biopsy of the orbit looked like a giant follicular lymphoma, and as you can see from the last biopsy, it looks like an inflammatory lesion of the submaxillary gland and the lymph nodes. I think we might call some of these lesions quasi-lymphomas or lymphatoid lesions.

DR. VERHOEFF: Was there a lot of fibrosis in the last one?

DR. BRALEY: Not so much in the last, but lots of fibrosis was present in the first biopsy.

DR. HEATH: This also enters the realm of the neuropotential, in the change in cells from one grade to another.

DR. VERHOEFF (closing): It is certainly refreshing to discover something from these pathologic processes. We try but we generally don't get anything.

CYANIDE INHIBITION OF CORNEAL RESPIRATION*

W. A. ROBBIE, PH.D., P. J. LEINFELDER, M.D., AND T. D. DUANE, M.D.
Iowa City, Iowa

Metabolic processes in the cornea have not been extensively studied, even though this tissue is well adapted to experimental investigation. The importance of such information in contact-lens fitting, corneal transplantation surgery, and similar fields is obvious. The avascular nature of the tissue and the low rate of oxygen consumption might suggest that the respiratory mechanisms involved are of a different nature than those in other types of mammalian tissue. Yet preliminary studies indicate that the essential components of certain dehydrogenase and cytochrome systems are present.¹

Inhibition of heavy metal catalysis by cyanide is a means of determining the activity of cytochrome oxidase in tissue respiration without disrupting the normal cellular structure. The drug is effective in low concentrations, is relatively specific in its action, and penetrates cell membranes readily. Herrmann, Moses, and Friedenwald¹ found that both cyanide and azide produced some inhibition of the intact bovine cornea, and that the addition of cytochrome-c to ground and dialyzed corneal tissue resulted in an increased oxygen uptake when hydroquinone or phenylenediamine were present as substrates. From these findings they concluded that the cytochrome system plays a part in the normal oxidative processes. Because the technique of controlling cyanide concentration in manometric experimentation has recently been improved² a more extensive study has been made to

determine how much of the normal respiration may be dependent upon an iron-containing enzyme complex.

METHODS

* Respiration measurements were made with Warburg manometers at 37.5°C., using flasks of about 7-cc. capacity. Each flask received one cornea, cut in half to prevent folding, from a rabbit of 1½ to 3 kilograms weight. Unless otherwise indicated, 1.0 cc. of pH-7.4 Ringer-phosphate buffer containing 0.2-percent glucose³ was added, and 0.6 cc. of 10-percent KOH solution or 10-percent Ca(OH)₂ suspension was placed in the center well on filter paper to absorb CO₂. In the experiments with cyanide, 0.1 cc. of neutralized KCN solution of 10 times the desired final concentration was added to 0.9 cc. of the buffer in the flask after the cornea had been added, and 0.6 cc. of the Ca(CN)₂-Ca(OH)₂ solution having an equivalent HCN tension² was placed on filter paper in the center well. In the experiments testing recovery from cyanide exposure the corneas were removed from the flasks at the end of the exposure period, rinsed in buffer, and returned to the washed flasks which now contained fresh fluid and center-well solution without cyanide.

Results are expressed in terms of dry weight. After each experiment, the corneas were rinsed in distilled water, laid on cover glasses, and weighed after drying to constant weight at 100° to 110°C.

RESULTS AND DISCUSSION

There is a definite and consistent inhibition of corneal respiration by the higher concentrations of cyanide, as shown in Figure 1. The oxygen consump-

*From the Department of Ophthalmology, College of Medicine, State University of Iowa. Aided by a grant from the John and Mary R. Markle Foundation. Read at the 16th scientific meeting of the Association for Research in Ophthalmology, Inc., Atlantic City, June 10, 1947.

tion of the control tissue is constant for more than six hours, and the corneas in cyanide have constant rates also at levels

Fig. 1 (Robbie, *et al.*). Oxygen consumption of whole rabbit corneas in various concentrations of cyanide.

which vary with the HCN concentration. This variation with concentration is illustrated more completely in Figure 2, which shows the inhibiting effects of a range of concentrations from 10^{-2} to 10^{-6} M.

A 10^{-4} M. HCN produces about 50 percent inhibition of respiration, and 10^{-3} M. leaves a residual oxygen consumption of less than 10 percent. It is apparent that a cyanide-sensitive enzymatic system is responsible for most of the normal corneal oxygen uptake.

Riboflavin deficiency produces corneal vascularization in rats,⁴ a finding which suggests that this vitamin is in some way involved in corneal oxidative metabolism. The riboflavin may play its part as a hydrogen carrier that is autoxidizable and reacts directly with molecular oxygen, or it may be used in a flavoprotein intermediate that serves as a connecting link between the dehydrogenases and the cyto-

chrome system. If its main function were the former and if it were a highly active factor in corneal metabolism, one would expect the respiration of the tissue to be quite insensitive to cyanide. However, if its main role is that of an intermediary which interacts with the cytochrome system, the oxygen consumption should be blocked by cyanide. The latter scheme of action appears the more probable.

Recovery of respiration upon the removal of cyanide is rapid. By the time a cornea is washed, returned to the manometer, and reequilibrated, recovery is almost complete. This is demonstrated by the experimental results presented in Figure 3. The cornea which was removed from the cyanide solution and washed after a 15-minute period of inhibition showed about the same oxygen uptake as the control (curve 1). The flask which was set up with HCN in the fluid but with KOH in the center well rather than a properly balanced alkali-cyanide mixture, lost HCN gas to the KOH so rapidly that again recovery was almost complete before a measurement could be made (curve 2). Pronounced inhibition occurred, however, when the center-well

Fig. 2 (Robbie, *et al.*). Variation in corneal respiration with HCN concentration. Each determination is for a 2-hour measurement period.

solution had an HCN tension equivalent to that of the fluid in the flask (curve 4). The importance of maintaining the proper concentrations of HCN gas in the manometer flasks by the use of center-well solutions of equivalent HCN tensions is obvious.

The nature of the linkage between cyanide and the ferric iron in cytochrome oxidase is not definitely known. If the combination were stable, recovery would occur only as rapidly as new enzymes were formed. The evidence presented in the recovery experiments illustrated in both Figures 3 and 4 indicates that the union in this particular tissue at least is very labile, and that a constant tension of HCN gas must be maintained in the manometer flask to inhibit a constant portion of the respiration.

In manometric work with tissue slices the limiting thickness which still permits adequate oxygenation is determined by the rate of respiration of the tissue, the

Fig. 3 (Robbie, *et al.*). Experiment demonstrating the importance of maintaining proper HCN equilibrium in manometric experiments. For explanation see text.

coefficient of diffusion of oxygen through the tissue, and the oxygen tension of the gas phase.⁵ The cornea exceeds the maxi-

imum thickness which is permissible with most other tissues; but, since both the rate of respiration and the rate of diffusion of gas undoubtedly vary in the different structural components, it is not practicable to determine the limiting thickness on a theoretical basis. Fischer⁶ has shown that the cornea normally uses oxygen directly from the air, and Lee and Hart⁷ found little change in oxygen uptake when rat corneas were measured in

contribute to the total by measuring the oxygen consumption of the whole cornea and that remaining after the epithelium and endothelium have been removed. Table 1 presents the results of a number of measurements on normal corneas and those which have had the two outer layers scraped off. The oxygen consumption of the stroma layer is one third that of the whole cornea. Since the weight of this portion is about 15 times that of the re-

Entire cornea	18	0.46	0.30-0.63
Stroma	22	0.15	0.07-0.25
Epithelium (estimated)	—	6 to 8	—

pure oxygen rather than air, indicating that respiration is maximum in air. In the present series of experiments several determinations were made using oxygen as the gas phase, and the rate of metabolism was found to be about the same as in air. The fact that the corneas may be used without the disturbance in normal structure which occurs when a tissue is sliced makes them favorable for certain types of long-term experiments. An indication of the normality of the tissue is given by the course of the oxygen uptake curves as shown in the figures. The control corneas may run for as long as 12 hours without a decrease in the rate of respiration.

The oxygen consumption of the intact cornea is due to the respiration of the epithelial and endothelial layers and to the relatively inactive stroma. It is impossible to strip off the two soft layers without injuring them drastically, but it is possible to estimate the amount of respiration they

maintaining layers it is apparent that its rate of metabolism is actually very low. The calculated value for the Q_{O_2} of the combined epithelium and endothelium is of the same order as that for other soft tissues such as liver, but the rate of respiration of the stroma is only one fortieth this amount. Since the stroma layer is primarily structural in function, a low level of oxygen consumption is probably sufficient to take care of its metabolic requirements. The functionally more active epithelium is ordinarily in close contact with air and direct diffusion can provide sufficient oxygen. Previous investigators who have measured the respiration of the rabbit cornea have reported somewhat higher values for the Q_{O_2} than that shown in Table 1. Kohra⁸ lists a figure of -1.56, and Orzalesi⁹ gives -2.09 for the Q_{O_2} values.

The scraped corneas are inhibited by cyanide to about the same extent as the intact ones, and 10^{-3} M. HCN produces

almost complete inhibition of respiration.

Living cells require continuous expenditure of energy for maintenance purposes. If this energy supply is blocked for a certain critical period, the cell dies. Most mammalian tissues may utilize carbohydrate by either aerobic respiration or glycolysis, and the cornea is apparently no exception. When atmospheric oxygen is available, most of the glucose substrate is metabolized to carbon dioxide and water. Under anaerobic conditions, possibly also when the eyes are closed and the oxygen tension is considerably reduced, the glucose breakdown proceeds only as far as lactic acid. Cyanide treatment produces the same result, because the normal oxidative pathway is blocked by cytochrome-oxidase inhibition. In either of these cases, the energy for survival may come from the glycolytic process and the cornea survives. With cyanide exposure, the glycolysis rate is increased because of inhibition of the Pasteur mechanism; the rate of corneal glycolysis in bicarbonate buffer is doubled by 10^{-3} M. HCN.

Figure 4 illustrates an experiment in which corneas were inhibited by cyanide for various periods and the recovery then observed. Although the respiration was depressed by the cyanide to 10 percent of the normal level for as long as seven hours, it came back immediately to the original level if glucose was present as substrate. The corneal cells apparently obtained their maintenance-energy requirements by glycolysis. The situation was quite different with those corneas that did not have added glucose as substrate. There was no recovery from a 7-hour exposure to cyanide even if glucose was added at the end of the period of inhibition. In this case the energy supply was probably interrupted at both the respiratory and glycolytic levels, the former by the cyanide and the latter by lack of substrate. The deprived cells

simply exceeded the tolerance limit for energy deprivation and were irreversibly affected.

Control corneas with no added glucose will respire uniformly for at least 12 hours at a rate which is the same or higher than those supplied with substrate. This respiration is almost completely inhibited by cyanide, indicating that it is probably due to carbohydrate oxidation. Since no glucose has been added, the cornea itself must contain the source material. It is quite possible that the mucoprotein which contains carbohydrate and comprises about 4 percent of the cornea¹⁰ is an adequate source for normal respiration for a long period. However, more than 10 times as much glucose must be converted by glycolysis to lactic acid to produce energy equivalent to that released when the substrate is completely oxidized. A source that might be adequate for respiration may soon be used up if the tissue depends only upon glycolysis for its energy. This rapid depletion of the carbohydrate reserve may depress the glycolytic process, and after seven hours in cyanide, as shown in Figure 4, the tissue can no longer recover. A comparable situation has been reported for brain tissue.¹¹ After exposure without substrate to anaerobic conditions there was an irreversible loss of glycolytic capacity due to nonregeneration of adenosine triphosphate.

SUMMARY

The respiration of the cornea is almost completely inhibited by 10^{-3} M. HCN, indicating that most of the oxygen consumption is probably mediated by a cytochrome-cytochrome oxidase system. A 10^{-4} M. cyanide produces about 50-percent inhibition. Recovery from cyanide exposure is rapid, and it is necessary to maintain a constant tension of HCN gas in the manometer flasks by the use of a properly balanced alkali-cyanide center-

well absorbing solution.

Most of the oxygen consumption of the intact cornea is due to the epithelial layer. The Q_{O_2} of this portion is about -6 to -8 , comparable to other soft tissue such as liver. The stroma which has been denuded of epithelium and endothelium by scraping has a very low rate, a Q_{O_2} of -0.15 .

Corneas may be 90 percent inhibited by cyanide for seven hours or longer and will recover quickly and completely upon removal of the cyanide, if glucose is present in the suspension fluid. If the fluid contains no substrate, there is no recovery after this exposure period.

DISCUSSION

DR. V. EVERETT KINSEY (Boston, Massachusetts): I would like to propose an alternative explanation to account for the increased effect of cyanide poisoning in the absence of glucose. I think, in general, the reversible poisons like HCN act by virtue of their ability to complete favorably for their substrate, in this case the substrate being cytochrome oxidase. Therefore, when you have glucose present, a certain number of molecules of glucol, if you like, combined with its substrate, the cytochrome oxidase, and when you have cyanide present, you have the competition of cyanide and glucose for the cytochrome oxidase.

I cannot cite the experiments, but I think there is a good deal of evidence in the literature that that is a mechanism which is fairly common, and I believe it

will account for your results equally well with the one which you propose.

DR. W. A. ROBBIE (Iowa City, Iowa): There is another type of experiment which has been performed that expresses in chemical language what I have said from the cellular standpoint. Some workers on brain metabolism found that in the absence of glucose, the glycolytic process, the ability to carry on glycolysis, was lost after a few hours. They found that this was due to the disappearance of adenosine triphosphate (ATP), and that the reaction was irreversible. After the tissue had gone for a certain length of time without any substrate, it was unable to produce this high-energy phosphate-bond linkage, which apparently is necessary for survival. Perhaps that is saying the same thing that I said in more chemical terms.

VISUAL EFFECTS OF TRIDIONE*

LOUISE L. SLOAN, PH.D., AND ANITA P. GILGER, M.D.
Baltimore, Maryland

A new synthetic compound, Tridione (3, 5, 5-trimethyloxazolidine-2,4 dione, Abbott) has recently been used as an anti-convulsant in the treatment of epilepsy. A number of papers¹ describing the results obtained with this new drug mention the fact that patients frequently complain of visual symptoms associated primarily with high illumination. Such symptoms are reported by a majority of adults and adolescents, occasionally by younger children. The only paper devoted specifically to the discussion of the visual phenomena is a brief note by Vail,² who reports that some patients experience difficulty in discriminating black or colors against light backgrounds and that visual acuity, although normal in low illuminations, may decrease to about 20/100 when the chart is illuminated to the customary level. It is reported that no external or ophthalmoscopic changes were found to account for these abnormalities in visual function.

The purpose of this paper is to report the results of a series of tests of visual function which provide further information as to the nature of the unusual visual phenomena associated with Tridione therapy. In preliminary studies, attempts were made to measure visual acuities for a wide range of illuminations including the high levels normally occurring outdoors. It was found that the previous state of adaptation of the eye and also its time of exposure to the brightness level at which acuity is measured are very impor-

tant factors and must be carefully controlled if reproducible measurements are to be obtained. Marked reduction in acuity can, for example, be demonstrated immediately after change in the illumination from a moderate to a high level and vice versa, in patients showing little or no impairment of acuity after exposure for 10 minutes or more to the brightness level at which acuity is measured. Therefore, in the experimental procedures finally adopted, tests of visual function were made primarily at two brightness levels, 2 millilamberts and 2,000 millilamberts, and emphasis was placed on measurements of the rate of recovery of visual function with continued exposure to each brightness level. Tests of both visual acuity and differential brightness sensitivity at the fovea were used in the experiments. Supplementary studies included determinations of the light threshold, tests of color discrimination at high intensity, and tests of sensitivity to flicker.

The subjects were seven patients from the Baltimore City Hospitals, one aged 30 years, the others between 56 and 68 years of age. Those with uncorrected vision of 20/30 or better did not wear glasses during these tests. All tests were made with the natural pupil. In most experiments only one eye was tested. Comparison of the results of monocular and binocular tests of acuity in two patients showed the results to be essentially similar. The dosage of Tridione was 1 gm. per day in six cases, 3 gm. per day in one case, that of R. DeC. The patients were studied while on Tridione for periods varying from two to nine months. Recovery from the visual changes after discontinuance of the drug was studied in three cases.

The authors are indebted to Miss Lorraine Wollach for assistance in giving the tests employed in this study.

I. VISUAL ACUITY

1. APPARATUS

Visual acuity was tested with a special series of charts composed of Landolt rings which, at a distance of five meters, corresponded to acuities of 0.1, 0.15, 0.2, 0.3, 0.4, 0.5, 0.6, 0.7, 0.8, 0.9, 1.0, 1.25, 1.50, and 1.75. In each size four positions of the break in the ring—up, down, right, and left—were used. The smallest size at which the patient could read correctly at least three of the four figures was taken as the measure of his acuity. Each group of figures was mounted on a piece of white cardboard, five inches in width,

Fig. 1 (Sloan and Gilger). Arrangement of equipment for testing visual acuity.

which could be slipped into guides at the center of a white cardboard screen. At five meters this screen subtended a visual angle of 11.5 degrees in the horizontal and 5.8 degrees in the vertical dimension (fig. 1). With these charts it is possible to make repeated rapid measurements of acuity without any possibility of memorizing by the patient. High intensities of illumination were obtained by means of two 500-watt photoflood lamps enclosed in bowl-shaped reflectors. The distance of these from the screen was adjusted to give an even illumination of the desired amount. Lower intensities of illumination

were provided by ordinary incandescent lamps in ceiling fixtures. A Macbeth Illuminometer was used to measure the brightness of the white background of the test charts.

2. RESULTS

A. Recovery of visual acuity at 2,000 millilamberts after adaptation to 2 millilamberts. In these tests the eye was first exposed for 10 minutes to the white screen illuminated to a brightness of 2 millilamberts. The illumination was then increased to give a brightness of 2,000 millilamberts, and measurements were made immediately and as rapidly as possible thereafter until acuity reached a constant level. When the increase in acuity was relatively slow it was possible to obtain very accurate measurements of the time required to reach each successive level of acuity. When recovery was rapid the successive stages could be measured only approximately.

The results of such tests are shown in Figures 2 to 5. In these graphs the times of exposure to 2,000 millilamberts are plotted on the abscissa, the corresponding acuities in logarithmic units on the ordinate. A logarithmic scale of acuities is used, rather than a linear scale, because it minimizes on the graph the unavoidable fluctuations in acuity which occur as the maximal level is approached.

In order to obtain comparative data on the normal rate of recovery of acuity, this test was given to four of the patients prior to Tridione therapy. While there may be, in normal subjects, a momentary reduction in acuity with sudden change in brightness from 2 to 2,000 ml., the time required to reach maximum acuity was less than one minute in every case and therefore could not be measured accurately by the procedures used in this study. Craik,³ using more accurate methods of measurement, found no significant reduc-

tion when acuity was measured within two seconds after change in brightness from about 1 to 1,000 ml.

The patients on Tridione, however, all showed a significant reduction in acuity immediately after exposure to the high brightness. Figure 2 gives typical recovery curves for each of the seven patients. In five cases the acuities were 20/200 or less after only one minute of exposure to the high brightness. With longer exposure, the acuity increased gradually, then reached a constant level. For most subjects this final level was equal to or better than that at 2 ml. Impairment of acuity is, therefore, only temporary and after sufficient time of

Fig. 2 (Sloan and Gilger). Rate of recovery of acuity after change from 2 to 2,000 ml. Typical curves for each patient. In normal subjects recovery is practically instantaneous.

Fig. 3 (Sloan and Gilger). Change in rate of recovery of acuity with duration of therapy. Subject F. S.

Fig. 4 (Sloan and Gilger). Change in rate of recovery of acuity with duration of therapy. Subject R. DeC.

Fig. 5 (Sloan and Gilger). Change in rate of recovery of acuity with duration of therapy. Subject G. T.

exposure to the high brightness there is no measurable defect. The recovery curves of two patients, W. C. and G. T., however, revealed a marked reduction in acuity even after adaptation for 10 or more minutes to the high brightness. The course of the recovery curves indicates that in these patients there was lasting impairment of acuity at the high brightness level, demonstrable even after long-continued exposure.

The rate and extent of recovery of acuity varied with duration of therapy. Five patients were tested at intervals while taking Tridione for periods of time varying from 7 to 28 weeks. Progressive changes in the recovery curves of three

patients illustrating different degrees of defect are shown in Figures 3 to 5. F. S. showed only a slight impairment of essentially the same degree after 14 and 18 weeks of therapy. For R. DeC., the rate of recovery was slower after 17 than after 14 weeks. The curves for 20 and 28

Fig. 6 (Sloan and Gilger). Changes in rate of recovery of acuity at 2,000 m. with duration of therapy. The time required to attain a given acuity is taken as an index of rate of recovery.

weeks of therapy, however, showed no further progressive impairment and in fact some evidence of improvement. G. T., followed for only 12 weeks on Tridione, showed marked impairment increasing in severity with duration of therapy.

The relationship between delay in recovery of acuity and duration of therapy is also shown in Figure 6. This chart gives the time required to reach a given level of acuity. The acuities chosen in each case are indicated on the individual curves. It is apparent from these curves

that for all five patients there was a gradual slowing in rate of recovery during the first seven weeks. The results for those followed for 14 weeks or more indicate that after long-continued therapy the recovery curves become approximately constant or show slight improvement, suggesting that the patients gradually developed a tolerance to the visual effects of the drug. It is of importance to determine in future studies whether patients with marked defects, such as were manifested by our subjects, W. C. and G. T.,

Fig. 7 (Sloan and Gilger). Improvement in recovery curves of acuity at 2,000 m. when Tridione was discontinued. Subject G. T.

also reach a constant level of impairment after long periods on Tridione.

Three patients, G. T., F. D., and J. K., whose recovery curves were measured 8 or 10 weeks after Tridione was discontinued, all had approximately normal rates of recovery at this time. Figure 7 shows for G. T. the gradual restoration to normal during a period of 10 weeks.

B. Recovery of acuity at 2 millilamberts after adaptation to 2,000 millilamberts. The results reported in the previous section indicated that Tridione produces a delay in the rate of light adaptation, as measured by tests of visual acuity. It might be expected, therefore, that the reverse change from high to low brightness would also produce a similar temporary

impairment of visual acuity. Studies were therefore made to test this assumption.

With change from 2,000 to 2 ml., normal subjects and patients tested prior to Tridione therapy reached a maximum acuity in less than one minute. A typical recovery curve for each of the six patients given this test is shown in Figure 8. The individual differences in rate of recovery correspond closely to those of the previous test. As before, F. S. and E. W. showed the most rapid rates, G. T. and W. C. the slowest. Adaptation of one eye to the high brightness did not produce any impairment in the unexposed eye when the latter was tested at 2 ml.

Recovery of acuity with change from high to low brightness differs in one important respect from that observed with change from low to high brightness. The final level of acuity at 2 ml., reached after continued exposure to this brightness, was in no case lower than the acuity prior

Fig. 8 (Sloan and Gilger). Rate of recovery of acuity after change from 2,000 to 2 ml. Typical curves for each patient. In normal subjects recovery is practically instantaneous.

to therapy. There is, therefore, no evidence of lasting impairment at the low brightness such as was observed in several patients at 2,000 ml.

C. Variation of acuity with intensity. It was shown in the previous sections that after adequate time of adaptation to the

brightness at which acuity was measured all subjects had normal acuity at 2 ml., while some showed significant impairment at 2,000 ml. Measurements of acuity at intensities between 2 and 2,000 ml.

Fig. 9 (Sloan and Gilger). Variation of acuity with light intensity. Subject G. T. In these tests the eye was adapted to each brightness before acuity was measured.

were made for G. T., one of the patients showing markedly reduced acuity at 2,000 ml. The tests at each intensity were continued until there was no further improvement in order to insure that maximal acuity was reached. The results are shown in Figure 9. Brightness in log units is plotted on the horizontal coordinate, acuity in log units on the vertical. At 10 ml., the acuity of 20/33 was equal to that prior to therapy. At 50 ml., it decreased to 20/70; at 1,000 ml., to 20/100. The fact that this patient complained of impaired vision only in outdoor illuminations is consistent with these findings, since indoor brightnesses are seldom greater than about 30 ml.

II. DIFFERENTIAL BRIGHTNESS SENSITIVITY

1. APPARATUS

The test for brightness discrimination employed gray strips (1° by 0.5°), mounted on a white background. The percent contrast depends upon the reflect-

ances of the strip and the background and is given by the formula: percent contrast equals $100(R_b - R_s)/R_b$ where R_b is the reflectance of the white background (0.88) and R_s that of the strip (0.80 to 0.024). The eight steps of contrast are

Fig. 10 (Sloan and Gilger). Arrangement of equipment for testing contrast (differential brightness) sensitivity.

9.1, 30.3, 50.0, 64.1, 76.5, 88.1, 95.4, and 97.5 percent. Three strips in different orientations were used at each contrast level. The patient was required to report whether the orientation of each strip was horizontal, vertical, or diagonal. The minimum perceptible contrast is taken as that at which the position of all three strips was named correctly. As in the acuity tests, the charts were shown at the center of the large white cardboard screen (fig. 10). The provisions for illumination of the chart and surrounding area were the same as those employed in the tests of visual acuity.

The minimum contrast perceptible by the normal eye is about two percent at high-brightness levels. In these studies no attempt was made to provide contrasts smaller than 9 percent because of the difficulties in measuring and standardizing smaller differences in reflectance. For this

reason and because the contrast steps are relatively large, this test equipment is suitable only for the measurement of relatively gross changes in contrast sensitivity.

2. RESULTS

A. Recovery of differential brightness sensitivity at 2,000 millilamberts after adaptation to 2 millilamberts. Four patients tested prior to Tridione therapy were all able to perceive the smallest contrast step (9 percent) within six seconds after a sudden change from low to high brightness. Figure 11 gives typical recovery curves for each of the six patients given this test while on Tridione. The two showing the most rapid recovery, F. S. and E. W., required more than three minutes of exposure to the high brightness before they were able to perceive the 9-percent contrast. Three patients with slower rates of recovery, F. D., R. DeC., and G. T., required from four to five minutes to detect the 30-percent contrast. The slowest rate of recovery was shown by W. C., who required about eight minutes to see the 30-percent contrast and

Fig. 11 (Sloan and Gilger). Recovery of contrast sensitivity after change from 2 to 2,000 ml. Typical curves for each patient. In normal subjects recovery is practically instantaneous.

could not get the next step (9 percent), after an exposure of 18 minutes to the high brightness. Figure 12 shows changes

in the recovery curves with time on Tridione for G. T., one of the patients with a relatively slow rate of recovery. After 12 weeks he was unable to distinguish a strip 50-percent darker than the background even after long exposure to the high brightness. Recovery of contrast sensitivity after the drug was discontinued is shown in Figure 13. In spite of the marked impairment after 12 weeks on Tridione, the results were approximately normal six weeks after it was discontinued.

B. Recovery of differential brightness sensitivity at 2 millilamberts after adaptation to 2,000 millilamberts. Three patients, were given this test prior to Tridione

Fig. 12 (Sloan and Gilger). Changes in rate of recovery of contrast sensitivity with duration of therapy. Subject G. T.

therapy. The time required to perceive the 9-percent contrast was less than 0.3 minutes in every case. Five patients were tested at intervals while taking Tridione. Recovery curves for W. C. are shown in Figure 12 to illustrate typical results. It may be seen that while there was a significant retardation in recovery, the rates were too rapid in this test to permit an accurate determination of the course of the curves. The times required by W. C. to perceive the 9-percent contrast varied from 1.5 minutes to 2.4 minutes in the different tests. The maximum times re-

Fig. 13 (Sloan and Gilger). Improvement in recovery curves of contrast sensitivity when Tridione was discontinued. Subject G. T.

quired by each of the five patients to reach this point on the curve are listed in Figure 14. F. S. and E. W., as in previous tests, showed the least deviation from normal and required only 0.5 and 1.1 minutes, respectively, to perceive the 9-percent contrast. These times, although short, probably represent a true impairment, since prior to therapy both patients required less than 0.1 minute.

Individual differences in the rate of recovery of brightness discrimination,

Fig. 14 (Sloan and Gilger). Rate of recovery of contrast sensitivity after change from 2,000 to 2 ml. The curves on the left show changes in rate of recovery for one patient, W. C., with duration of therapy. The tabulated data on the right give the maximum times required by different patients to perceive a 9-percent contrast. In normal subjects recovery is practically instantaneous.

with change from high to low brightness and the reverse, correspond closely to the individual differences in rate of recovery of visual acuity. The more rapid recovery of contrast sensitivity than of acuity may be attributed in part to the fact that the smallest contrast measured is greater than the minimum which can be perceived by the normal subject. Because of this, recovery of contrast sensitivity could not be followed to its maximum.

The general similarity in the results of the two types of test suggests that poor brightness discrimination rather than impaired resolving power of the retina is the primary factor responsible for the reduction in visual acuity. This is supported by the statements of the patients that they could not see the test letters immediately after increase in the illumination because everything looked white.

III. TESTS OF THE LIGHT THRESHOLD

The instrument and procedure used in these studies has been described in detail elsewhere.⁴

1. THRESHOLD OF THE DARK-ADAPTED EYE

The thresholds of the fully dark-adapted eye were measured at 19 different locations in the horizontal meridian, extending from the fovea to the far periphery both nasally and temporally. The average of these 19 thresholds, designated hereafter as the "horizontal-meridian threshold" provides a sensitive index of changes in the general level of sensitivity of the rod mechanism throughout the retina.

Three patients, E. W., F. D., and W. C. were tested before and during Tridione therapy. The horizontal-meridian threshold of E. W. before therapy was 5.32 (log micromicrolamberts); after three weeks on the drug, 5.10; after 16 weeks, 5.0. The thresholds of F. D., in four successive tests during a period of

four months prior to therapy, were 5.30, 5.22, 5.13 and 5.22; after eight weeks on Tridione, the threshold was 5.29. In these two patients the evidence is unequivocal in showing no significant increase in rod thresholds at a time when tests of visual acuity and brightness discrimination revealed marked impairment of cone function. The data for the third patient, W. C., are less satisfactory because of the greater variability in successive tests. The horizontal-meridian threshold prior to therapy was 5.43; after one week on the drug, 5.73; after two weeks, 4.92. Tests of acuity and brightness discrimination showed greater impairment of cone function after two weeks than after one week of therapy; whereas, the increase of 0.3 log unit in the rod threshold after one week was not confirmed in the test made after two weeks. It may be concluded, therefore, that in this case also, Tridione had no measurable effect on the rod thresholds of the dark-adapted eye.*

2. RATE OF DARK ADAPTATION

Tests of differential brightness discrimination, it will be remembered, showed a slight delay in rate of recovery of sensitivity at 2 ml. after adaptation to 2,000 ml. A similar delay in rate of recovery of sensitivity of the cones or the rods or of both, might therefore be expected when the brightness threshold in-

* The horizontal-meridian thresholds of these patients are all close to the upper limit of normal. The thresholds of normal individuals, corrected for size of pupil, range from 3.8 to 5.1. Without pupil correction a somewhat greater range is to be expected. It was impossible in this study to make such corrections because photoflash bulbs for photographing the pupil could not be obtained. It is possible, therefore, that small pupils account for the relatively high thresholds. Although the patients were on institution diets perhaps low in vitamin A, this factor can be ruled out in the case of F. D., since after the first light-sense test he received daily supplements of vitamin A during the entire period of the tests.

stead of the just noticeable difference in brightness is used as a measure of sensitivity.

The rate of dark adaptation at the fovea was determined for one patient, E. W., before and during Tridione. The results are shown in Figure 15. The increase in light thresholds after 3 and 16 weeks on Tridione is slight and perhaps not significant in view of the normal day to day variation in threshold measurements. It is, however, of about the magnitude that would be expected from the results of the tests of differential sensitivity for this patient. Before therapy the time required to perceive a 9-percent contrast at 2 ml. after adaptation to 2,000 ml. was less than 0.1 minute; after 10 weeks on Tridione, it was 1.1 minute. It may be seen from Figure 15 that the light threshold reached in 0.6 minute prior to therapy is reached in about 1.7 minute. The delay in reaching a given level of sensi-

shown in Figure 16. This patient shows no significant change in cone adaptation since the curve obtained during therapy lies within the range of variation observed in the control tests. In the test of differ-

Fig. 16 (Sloan and Gilger). Rate of dark adaptation at 15 degrees in the nasal field after preadaptation to 1,100 ml. A 1-degree white test field was used. Subject F. D.

Fig. 15 (Sloan and Gilger). Rate of dark adaptation at the fovea after preadaptation to 1,100 ml. A 1-degree white test field was used. Subject E. W.

tivity is therefore about the same in the two tests.

Similar tests of the rate of dark adaptation, but at 15 degrees in the nasal field instead of at the fovea, were given to another patient, F. C. Four tests prior to Tridione and one test after 8½ weeks of therapy were made. The results are

entail brightness sensitivity given on the same day, however, he required 4.2 minutes to detect a 9-percent difference in contrast. This difference in the results of the two tests may indicate a greater impairment of the foveal than of the parafoveal cones. The second section of the adaptation curves, which measures the rate of adaptation of the rods, likewise shows no significant change with Tridione. Here, however, the variation in the data obtained prior to therapy is as much as 0.9 log unit, so that in this patient slight changes in rate of adaptation of the rods could not have been detected.

Tests of the light threshold, therefore, did not reveal any marked impairment of cones or rods, either during adaptation to darkness or after dark adaptation was complete. It is possible that the rods may show impaired function at higher intensities, such as was demonstrated in the case of the cones by other tests. Since there are no retinal areas containing rods

alone, practical difficulties arise in completely separating rod and cone function at intensities well above the rod threshold. Determinations of the variation in brightness or flicker sensitivity with variation in intensity in the scotopic range, if made before and after Tridione therapy, might however provide an answer to this problem. It is planned to make such tests in future studies.

IV. COLOR DISCRIMINATION

1. GENERAL OBSERVATIONS

The Ishihara Pseudo-isochromatic Plates, viewed in an illumination of about 20 foot-candles, were read correctly by all patients. This finding ruled out congenital red-green color deficiency and was consistent with the results of other tests showing that color discrimination is impaired only at high intensities. The visual fields for 1-degree blue and red test objects were normal when determined under standard conditions with a Brombach perimeter. When, however, a white background was substituted for the black perimeter arc and the illumination was increased from the standard value of 10 foot-candles to about 200 foot-candles, 1-degree blue and red test objects were recognized only at the fixation point. Under these experimental conditions, normal controls do not show any similar contraction of the color fields. This finding indicates that visual impairment is not limited to the foveal cones, and probably involves cone function throughout the entire retina. Further evidence of anomalous color perception is the erythroptopia at high illuminations reported in the early stages of therapy by three patients. During the tests of brightness discrimination, one patient volunteered the information that the gray strips on the white background and other darker areas in the field of view appeared pink.

2. SPECIAL TEST OF COLOR VISION

Additional information as to the nature of the distortions of color perception was obtained from a special test of color discrimination similar to that used to measure brightness discrimination.

A. Apparatus. The equipment may be described briefly as follows: oblong strips (1° by $\frac{1}{2}^\circ$) of red, green, blue, and yellow are shown on backgrounds of approximately the same reflectance as the strip. Each background is a 1.6-degree square, either gray or a chromatic color differing from the test strip. The strips on their respective backgrounds are shown two at a time in an aperture in a white screen illuminated to a brightness of 2,000 ml. The brightnesses of the colors are somewhat less, the exact values depending on their reflectances. The test strips and their backgrounds were selected from standard Munsell pigment papers. In each of the four hues, strips of low, moderate, and high chroma (saturation) are used. The Munsell specifications for the 24 combinations of strip and background are listed in Table 1. These define the colors of the papers when illuminated by light of daylight quality. In illumination from photoflood lamps such as was used in most of our tests, there is probably a considerable decrease in chroma of the blues, and some increase in that of the reds.⁵

B. Results. In tests made prior to Tridione therapy, all the colored strips were identified correctly with the exception of green, which was occasionally called blue or greenish-blue particularly when on a yellow background. Of the five patients tested at a high illumination while on Tridione, all but one, F. S., showed significant abnormalities in color discrimination. The findings summarized in Table 1 illustrate the type and degree of impairment observed. The tests were given after 5 to 20 minutes' exposure to 2,000 ml. It

was not feasible to make accurate tests of changes in color discrimination with time of exposure to the high brightness because of the length of time required to present all the color combinations. It was,

were usually reported as blue, gray, or white. Calling the green strip blue may not be of significance since this error was also made prior to therapy. In Group III, the most saturated blue (chroma 12) was

nevertheless, apparent that color discrimination improved somewhat with continued exposure. The results in Table 1 represent the most marked defects observed in each patient.

In Group I, composed of red strips on gray or yellow backgrounds, the strip was sometimes not seen at all, indicating that it was a close match to the background. In other cases the strip was reported as yellow, white, or gray. In Group II, green strips on various backgrounds, the strips

always identified correctly. Blues of lower chroma were reported as white by two patients. In Group IV, yellow strips on gray backgrounds, none of the patients made any errors. In the yellowish illumination from the photoflood lamps, yellows are of higher saturation than blues of the same nominal chroma. For this reason it cannot be definitely concluded from these findings that there is a greater impairment of sensitivity to blue than to yellow. The findings do suggest, however, that

perception of red and green is more impaired than perception of blue and yellow.

V. FLICKER SENSITIVITY

Tests of sensitivity to flicker, while not directly related to the visual discriminations required in the ordinary use of the eyes, may nevertheless be of aid in explaining the visual impairment produced by Tridione. The critical flicker frequency, or rate of alternation of dark and

crimination, they may contribute both directly and indirectly to our knowledge of the effects of Tridione on vision.

1. APPARATUS FOR MEASURING CRITICAL FREQUENCY OF FLICKER

The arrangement of apparatus is shown diagrammatically in Figure 17. S_1 and S_2 are white screens, reflectance 0.88, which may be illuminated to any desired brightnesses. The square aperture, A , through which the observer views S_2 , serves as the test field; the square field, S_1 , as the surround. The test field and surround subtend visual angles of 1 degree and 10 degrees, respectively. A rotating, sectored disc, D , is located directly behind aperture, A . The closed sectors of the disc are painted a matt black (reflectance 0.06).

This apparatus differs in two ways from that usually employed⁶ in measuring critical flicker frequency (c.f.f.) in man. First, the illumination of the test field is not cut off simultaneously over its entire area. Second, the light illuminating the surround also falls on the black-sector disc. In Series A, in which the surround is matched to the test field at each intensity, the dark phase of the flickering light has a brightness about 3.5 percent of that of the light phase. In Series B and C, in which the surround is maintained at a constant low brightness of 1 ml., the dark phase is only 0.07 ml. The experimental conditions of this study are therefore somewhat similar to those frequently used in animal experiments in which moving black and white stripes provide the flicker stimulus.⁷ The findings may perhaps differ slightly from those obtained when the entire flicker field is reduced simultaneously to zero brightness. Valid comparisons are nevertheless possible between the data for normal controls and those for patients on Tridione when both are tested under identical conditions.

Fig. 17 (Sloan and Gilger). Arrangement of equipment for measuring critical frequency of flicker. S_1 , illuminated surround. A , 1-degree square aperture through which subject views illuminated screens, S_2 . D , sectored disc. M , motor. T , tachometer. L , lamps in reflectors.

light flashes at which the sensation of flicker disappears, has been extensively investigated under a number of experimental conditions. Such studies have been made not only in man, but also in many of the lower animals which respond with characteristic reflex movements to a flickering light. It is possible that a final explanation of the effects of Tridione on the visual mechanism may require parallel experiments on animal subjects. Since measurements of critical flicker frequency in human beings can more easily be duplicated in animal experiments than can measurements of acuity or brightness dis-

2. RESULTS

Series A. In the first series of experiments the c.f.f. in cycles per second was measured at fusion brightnesses of the test field ranging from about 1 to 1,000 ml. The flicker disc was composed of equal open and closed sectors. The fusion brightness of the test field was therefore one half the brightness of the illuminated screen S_2 . The brightness of the surround, S_1 , was matched in each case to the brightness of the test field at fusion.

Results are given in Figure 18 for four normals and three patients on Tridione. In normal subjects, the c.f.f. increased with increase in brightness of the test field up to about 300 ml. (2.5 log units), then became constant or decreased slightly. In the three patients on Tridione, the c.f.f. followed a normal course up to about

flicker sensitivity. It is of interest that, although marked impairment of sensitivity to flicker persisted after adaptation to high brightness, the visual acuity and

VARIATION IN CRITICAL FLICKER FREQUENCY WITH BRIGHTNESS OF TEST FIELD, 50% LIGHT TIME MATCHING SURROUNDS

Fig. 18 (Sloan and Gilger). Variation in c.f.f. with variation in fusion brightness of the test field when the surround is of the same brightness as the test field. The lowest curve in each group is in the correct location. The others are shifted upward in steps of 10 units on the vertical ordinate.

30 ml. (1.5 log units) then decreased at higher brightnesses.

The measurements of c.f.f. charted in Figure 18 are those obtained after adaptation to each brightness for the time necessary to reach a constant level of

differential brightness sensitivity of these three patients nevertheless showed complete recovery after adequate light adaptation. In one case, R. DeC., alternate measurements of acuity and c.f.f. were made at the same high brightness until both reached constant levels. This test proved conclusively that, under identical experimental conditions, visual acuity may be normal and sensitivity to flicker markedly reduced.

Series B. In the second series of flicker experiments the brightness of the surround was maintained at a constant low value of 1 ml. The other experimental conditions were the same as in Series A. Figure 19 gives the c.f.f.-Log-I curves for four controls and three patients on Tridione. The curves of normal subjects were in general similar to those obtained by them with matching surrounds, but showed slightly lower values of c.f.f. throughout, and a more marked drop at high intensities. These differences are in

accord with the results of previous investigations.⁸

The curves of the patients on Tridione, however, differed markedly from normal. Their irregular course suggests that two opposing factors were at work, one producing a decrease, the other an increase

Fig. 20 (Sloan and Gilger). Difference between the values of c.f.f. for a normal subject and for each patient on Tridione. The data are obtained from the curves of Figure 19.

in c.f.f., with increase in intensity. This is more clearly evident in a graph showing, not the actual values of c.f.f. at each intensity, but the difference between these values and those of a normal subject. Such data are shown for each of the three patients in Figure 20. Impairment in flicker sensitivity, as indicated by the degree of deviation from the curve of a normal subject, increased regularly for all three patients with increase in intensity up to 2 or 2.5 log units. At still high intensities there was a gradual return toward normal. The data obtained with matching surrounds, on the contrary, showed gradually increasing impairment with increase in intensity and no evidence of recovery at high intensities. The difference in the results of the two tests is apparent in Figure 21 where both curves are shown on the same graph for one patient who was given the two tests on the same day. The most marked difference occurred at the highest intensity, 1,740

ml. (3.24 log units), where the c.f.f. was 39.6 when determined with a low surround, but only 20.6 when determined with a matching surround. Additional experiments indicated that the effect of the different surrounds on the c.f.f. cannot be attributed to the difference in level of light adaptation. When the eye was adapted to 1 ml., and the surrounding field was suddenly increased to match the test field, the c.f.f. dropped immediately from 39.6 to 8.0, then rose gradually to 20.6 as the eye became adapted to the higher brightness. Conversely after adaptation to the higher brightness, with sudden decrease in the brightness of the surround to 1 ml., the c.f.f. rose immediately from 20.6 to 32.5, then showed a further rise to 39.6 as the eye became adapted to the lower brightness.

It appears, therefore, that the brightness of the surrounding field has an im-

Fig. 21 (Sloan and Gilger). Comparison of the results when the brightness of the surround is maintained at a constant value of 1 ml., and when it matches the test field at each intensity. Subject R. DeC.

mediate and direct effect on sensitivity to flicker. Some process of facilitation may occur when the surround is much lower in brightness than the test field, and conversely a high brightness of surround may have an inhibitory effect on flicker discrimination. These effects, it will be

noted, are the reverse of those occurring in the normal eye. Such interaction between different retinal areas when manifested practically instantaneously cannot easily be explained in terms of photochemical changes and is, therefore, usually attributed to processes involving lateral connections in the neural layers of the retina.

Series C. In the two previous tests, the dark phase was 50 percent of the complete cycle. A third series of tests investigated the effect of variation in the relative lengths of the dark and light phases. Flicker discs with different sizes of closed sector provided dark-times of 10, 25, 50, 75 and 90 percent. Other experimental conditions were the same as in Series B.

Fig. 22 (Sloan and Gilger). Variation in c.f.f. with variation in fusion brightness of test field for five different values of dark-time. Normal subject.

It has been shown in previous studies by Crozier, Ross, and others⁹ that for constant brightness of the test field, the c.f.f. increases with increase in the dark-time. Our data, both for normal subjects and patients on Tridione, are in agreement with those of Ross, who found that fusion brightness and dark-time are inde-

pendent variables whose effects on the critical frequency of flicker are additive. Data for a typical normal subject illustrating the effect on the c.f.f.-Log-I curve of change in dark-time are shown in

Fig. 23 (Sloan and Gilger). Replot of data of Figure 22 after applying corrections required to superimpose the data for five dark-times. The symbols have the same meaning as in Figure 22.

Figures 22 and 23. In Figure 22 it may be seen that the five curves for different dark-times follow approximately parallel courses, suggesting that increase in dark-time merely shifts the curve upward without changing its shape. In order to test this assumption the same data have been replotted in Figure 23 after applying suitably chosen corrections to compensate for the effect of increase in dark-time on the c.f.f. It may be seen from Figure 23 that it is possible to draw a single curve through the points representing the corrected values of c.f.f. for all five dark-times. The same treatment of the data of a second normal subject gave essentially similar results.

Similar tests were given to two patients on Tridione (figs. 24 and 25). Here, too, the data for different dark-times can be fitted approximately to single curve by subtracting a constant from the values of c.f.f. for each dark-time. The patients on Tridione, however, showed a smaller in-

crease in c.f.f. with increase in dark-time. Table 2 gives these data for the normal subjects and the patients on Tridione. For the two normals, the increase in c.f.f. with

reached, c.f.f. decreased with further increase in intensity. (2) When the surround was maintained at a constant low brightness and only the test field was increased in intensity, a similar decrease in c.f.f. occurred at intermediate intensities. At still higher intensities, however, the c.f.f. increased again and approached a normal value at an intensity of 3 log units or greater. Impairment in foveal sensitivity to flicker at high intensity was greatest, therefore, when a large area of

Fig. 24 (Sloan and Gilger). Superimposed data for five dark-times. Subject F. S. Symbols as in Figure 22. The normal curve from Figure 23 is shown for comparison.

increase in dark-time from 10 percent to 90 percent was 19.8 and 20.0 cycles per second. The two patients on Tridione showed increases of only 10.9 and 14.0 cycles per second. The results suggest that the rate or extent of recovery taking place during the dark phase was decreased in some way by Tridione.

The effects of Tridione on sensitivity to flicker, demonstrated in these studies, may be summarized as follows. (1) With increase in intensity of both test field and surround, c.f.f. at first increased, but more slowly than normal. When an intensity of about 300 ml. (log I-2.5) was

Fig. 25 (Sloan and Gilger). Superimposed data for three dark-times, 90, 50, and 10 percent. Subject R. DeC. Symbols as in Figure 22. The normal curve from Figure 23 is shown for comparison.

the surrounding retina was also exposed to the high intensity. (3) With increase in the relative length of the dark phase of the flicker cycle, the increase in c.f.f. was not as great as that observed in normal subjects. (4) The abnormalities in flicker

sensitivity observed in patients on Tridione do not appear to be closely related to the impairment in visual acuity, brightness and color discrimination observed in these patients. Flicker sensitivity may, for example, show marked impairment under experimental conditions in which visual acuity is not affected. One patient, F. S., with very marked defects in the flicker tests showed only slight impairment in the other group of tests.

VI. ADDITIONAL STUDIES

Before Tridione therapy was commenced, external, ophthalmoscopic, and slitlamp examinations were made on each patient. Most of the patients showed a faint lenticular haze and slight retinal vascular changes of an arteriosclerotic or arteriolar sclerotic nature. Other than these, no pathologic findings were present in the seven patients studied intensively. During the time which these patients were followed, there was no change in these findings except in one case where there was a definite slight increase in fine cortical opacities during the course of nine months. All the patients studied in the previous tests had corrected visual acuities of 20/20 or better in each eye, and read Jaegar 1 with correction.

Two additional patients on Tridione died from other causes, one while on therapy and the other 48 hours after it was discontinued. Because of their bedridden state, extensive studies of visual function had not been made. Sections of the posterior segments of these eyes were obtained and studied with the help of Dr. Jonas S. Friedenwald. As was anticipated, the delay in fixing the eyes due to the time required to secure the autopsy permits resulted in sufficient autolysis to mask any slight changes in the nerve cells and fibers which might have been seen with special staining techniques. No pathologic findings were present except those

diagnosed ophthalmoscopically prior to therapy with Tridione and those due to the terminal systemic disease. The eyes of one of the patients who died of uremia showed on microscopic examination: "Slight septic choroiditis; retinal arteriosclerosis." Retinal arteriosclerosis was the diagnosis made before Tridione was given. The other patient died from bronchogenic carcinoma. Ophthalmoscopy before Tridione revealed pallor of the discs, O. U., and there was no observed change during therapy. The eye-pathology diagnosis was: "Slight septic choroiditis; partial optic atrophy."

Subjective sensations of the patients while on therapy were of interest. While adapting to a high intensity of illumination, most reported that "white clouds" were passing in front of their eyes. Occasionally the clouds would roll away so that they could see better and then would close in for a short time again. Three patients complained of erythropsia in outdoor illuminations; this disappeared on continued use of the drug. Our patients found that their subjective symptoms were alleviated by wearing dark glasses in outdoor illuminations.

SUMMARY AND CONCLUSIONS

The significant effects of Tridione on visual function demonstrated in this study may be summarized as follows:

1. Acuity, brightness sensitivity, color discrimination, and sensitivity to flicker showed temporary impairment in all patients tested, when both the foveal test field and a surrounding area of 6 to 10 degrees were illuminated to a high brightness. While these findings all point toward impairment in function of the foveal cones at high brightnesses, supplementary tests indicated that the defect was not a localized central scotoma but involved cone function throughout the entire retina.

2. With continued exposure to the high brightness there was gradual improvement in visual function. In 5 of 7 patients, acuity and brightness discrimination reached normal values after about 10 minutes. Sensitivity to flicker, although it improved, continued to show significant impairment after long adaptation to the high brightness in patients who had recovered normal acuity and normal brightness sensitivity.

3. Two of the seven patients showed a lasting impairment of both acuity and brightness sensitivity at 2,000 ml. Tests of acuity at brightnesses below 2,000 ml. indicated that significant lasting impairment may extend to brightness levels of 50 ml. or less.

4. All patients showed a temporary impairment in acuity and in brightness sensitivity at 2 ml. after previous adaptation to 2,000 ml. None showed lasting impairment after adaptation to the low brightness.

5. Impairment in foveal sensitivity to flicker at high intensities was less marked when the brightness of the surrounding fields was 1 ml. and only the 1-degree test field was of high brightness.

6. Increase in the length of the dark phase of the flicker cycle produced less

than the normal increase in sensitivity to flicker at the fovea. This was true at low as well as at high brightnesses of the test field.

7. The findings in patients studied for more than three months while on Tridione indicate that tolerance to the visual side effects develops with continued medication. Patients reexamined after the drug was discontinued showed no evidence of any visual impairment after 10 weeks without Tridione.

The action of Tridione on the visual mechanism probably does not occur posterior to the chiasm, since exposure of one eye to a high brightness does not produce these effects in the unexposed eye. If the action were at the level of the optic nerve, it is unlikely that cone fibers alone would be affected. It seems probable, therefore, that the drug produces its effects at the retinal level. For the most part, the phenomena suggest that the neural layers of the retina rather than the photochemical processes are involved. Studies on animals of the effects of Tridione, using the electroretinogram, measuring the optic-nerve discharges, and so forth might, therefore, be of aid in explaining the mechanism of the visual defects.

THE EFFECTS OF DI-ISOPROPYL FLUOROPHOSPHATE VAPOR ON THE EYE*

W. H. ALDRIGE, AND HUGH DAVSON, PH.D.

London, England

EDWIN B. DUNPHY, M.D.

Boston, Massachusetts

AND

GEORGE I. UHDE, M.D.

Louisville, Kentucky

The fluorophosphates have an eserine-like effect, increasing the activity of the parasympathetic system. In the eye, this is manifested in a pronounced miosis, reduction of the intraocular pressure, conjunctival hyperemia, aching of the eyeball, and mistiness of vision, the latter effect being due in all probability to increased tonus of the ciliary muscle. General effects include tightness in the chest, headache, rhinorrhea, and diarrhea.

Recent reports of the effect of diisopropyl fluorophosphate (D.F.P.) on

the eye and its use in the treatment of glaucoma have been published by Leopold and Comroe,^{1,2} and by McDonald.³ An investigation into the potentialities of D.F.P. vapor as a chemical-warfare agent was undertaken by us during 1943.* With the lifting of security regulations it was thought wise to publish it in part since it contains certain basic observations on the effects of this compound on the eye.

EXPERIMENTAL

1. *Production of the vapor concentration.* Air containing di-isopropyl fluorophosphate vapor was obtained with the constant-flow device.

Owing to the lengthy analytical procedure, no analysis of the vapor concentration was carried out immediately before exposure, as with our earlier ex-

* This work was carried out under the Physiological Section (A. Fairley, head) of the Chemical Defence Experimental Station, Porton, England (Porton Report 2592). Since these experiments were designed primarily to assess the degree of visual impairment, no observations on the reduction of intraocular pressure were made.

periments, but samples of the flow were taken after each exposure for subsequent analysis. This procedure was justified by the comparatively minor eye effects which were expected and by the high degree of predictability of the vapor concentrations from the tap settings of the instrument. Very rarely did the actual dosage differ from that intended by more than a few percent. Difficulty was encountered with the decomposition of the di-isopropyl fluorophosphate presumably through the agency of moisture and alkali from the soda-glass beads in the bubbler. Bubblers were constructed with Pyrex bodies and with phenolformaldehyde resin chips in place of the beads, and the air used in the constant-flow device was dried over calcium chloride before it entered the bubbler. The stability of the di-isopropyl fluorophosphate was greatly enhanced by this procedure and consistent values for the saturation concentration could readily be calculated from the results. At 13.2°C., a saturation concentration of 3,470 mg./m³, corresponding to a vapor pressure of 0.337 mm. Hg, was observed.

2. *Determination of the vapor concentration.* The concentrations of di-isopropyl fluorophosphate in the vapor were estimated using the method for fluorine determination. Good reproducibility was obtained.

3. *Exposure to the vapor.* A modified respirator face-piece, which permitted the passage of vapor over the eye while enabling the individual to breathe pure air, was employed.

Both eyes were exposed, except in a few instances where corneal and iris changes were being observed. Exposure times were kept constant at five minutes and the concentrations varied in different experiments from 8 to 50 mg./m³, giving dosages (Ct)* in the range 40 to 250 mg. min/m³.

4. *Clinical examinations.* Parasympathetic stimulation may possibly influence: (a) Pupil size; (b) visual acuity; (c) the near point of accommodation; (d) the threshold of scotopic or rod vision by virtue of the diaphragmatic action of the iris; (e) the tone of the superficial and deep vascular layers of the eye, causing conjunctival hyperemia and uveitis.

Finally, the general toxic action of di-isopropyl fluorophosphates might cause corneal changes such as edema and infiltration (f). The various factors (a) to (f) were investigated as follows:

FACTORS INVESTIGATED.

(a) *Pupil size.* The individual was placed in a dimly illuminated room such as to produce a brightness of about 1.15 equivalent foot-candles on the yellowish-white walls; he was told to look at the distant wall (6 meters away) and a scale was held in front of the eye and the pupillary diameter measured. In one experiment photographic methods were also used and these will be described later.

(b) *Visual acuity.* Vision at 6 meters was measured with a Snellen chart illuminated to give a brightness of its white background of 17 foot-candles, and the lowest row of letters which could be read was noted.

(c) *Accommodation.* The near point of accommodation was determined fairly crudely by holding a meter scale perpendicular to the malar bone and instructing the individual to bring a test-type card closer and closer until the fine type was blurred; he was then told to move the card back until he could just read the type distinctly, and the distance from the malar bone to this final position was recorded.

* "Ct" is used in chemical warfare to express unit dosage. Ct denotes the concentration of the gas in milligrams per cubic meter times the period of exposure in minutes.

* Diameter of pupil in mm.

The mean of three determinations on each eye separately was taken. If the individuals had any refractive error, this was corrected with appropriate lenses before the test was made.

(d) *Scotopic visual threshold.* The individual was light adapted for five minutes with a bright source of light in a dark room. The light was switched off and immediately afterward the threshold of light sense was recorded continuously for half an hour on the Craik Adaptometer.

(c) *Vascular tone.* The conjunctiva was

examined for reddening, and the fundus observed with the ophthalmoscope. In selected individuals, a slitlamp examination of the iris was made.

(f) *Corneal changes.* Selected individuals (exposed to high dosages) were examined under the slitlamp.

RESULTS

(a) *Pupil size.* (See Table 1). In general, miosis began about 10 minutes following exposure; in most cases it had reached its maximum in 24 hours, although in dosages above 116 mg. min/m³

full constriction was present one hour after exposure. The miosis usually remained constant for 48 hours after which it began to abate somewhat. In the higher dosages (above 116 mg. min./m³), there was usually no sign of relaxation of mio-

Fig. 1. (Aldrige, Davson, *et al.*). Pupil sizes after dark adaptation. Only the left eye has been exposed to D.F.P.

sis even after 72 hours. It was impossible to follow up all the subjects to ascertain how long their miosis lasted, since they were military personnel and were allowed away from their units for a few days only. However, in some preliminary experiments, it was noted that the pupils did not regain their normal size in the light for five to six days, even with moderate dosages.

The miosis following D.F.P. exposure

may be largely due to an exaggeration of the normal light reflex following the inactivation of cholinesterase; if this were true it might be expected that the miosis would relax after, say, 30 minutes to one hour in the dark. At the end of some of the dark-adaptation tests, at which time the individuals had been in the dark for some 30 minutes, an attempt was made to measure the pupils with the aid of a dim red lantern. The impression was gained that within a few hours of the exposure no relaxation of miosis occurred; whereas, after 48 hours it appeared that some increase in pupil diameter took place dur-

Fig. 2 (Aldrige, Davson, *et al.*). Subject Q. A flashlight photograph of 1/30,000-second exposure, taken 48 hours after the eye was exposed to D.F.P. The eye, dark adapted for 10 minutes, shows miosis and engorgement of the conjunctival blood vessels. Only the left eye was exposed to D.F.P.

ing dark adaptation. A more accurate experiment was carried out as follows:

The left eyes only of three men were exposed to a dosage of 100 mg. min./m³, and two hours later they were kept in a dark room for one hour; their eyes were then photographed in the dark by flashlight of 1/30,000-second duration. The same procedure of dark adaptation and flashlight photography was repeated 24, 48, and 96 hours later. The results are shown in Figure 1.

There is no doubt that the miosis can be pronounced, even after one hour's dark adaptation, and that it persists to some extent for as long as 96 hours after exposure with, however, a progressive relaxation from day to day. The persistence of the miosis for one hour in the

* Visual acuity (corrected).

† O.S. only exposed.

complete absence of light stimuli tends to confirm the belief, generally held, that the pupil size is normally controlled by a balance between tonic constrictor and dilator impulses; the potentiation of the tonic-constrictor impulses by the eserine-like action of di-isopropyl fluorophos-

phate is sufficient to maintain a pronounced miosis even in the absence of light stimuli.

(b) *Visual acuity.* (See Table 2). There was practically no impairment of visual acuity among the 16 subjects used for this test.

(c) *Accommodation.* (See Table 3). The effects of dosages of D.F.P. ranging from 40 to 191 mg. min./m³ on the position of the near-point of accommodation were noted. It was found the near-point moved inward a few centimeters in all cases, a finding which suggests that there is an increased development of tension in the ciliary muscle during accommodation; the absence of any serious impairment of distance vision, however, indicates that there is no uncontrollable spasm of this muscle with the concentrations employed.

(d) *Scotopic visual threshold.* (See Table 4). The threshold brightness required to stimulate the light sense of dark-adapted individuals before and after exposure to D.F.P. was recorded. In all cases the threshold increased one to two

hours after exposure, and later tended to return to normal. If the pupil size before exposure were 6 mm. and after exposure 1.5 mm. in diameter, the amounts of light entering the eye in the two conditions would be in the ratio of about 16 to 1 and one would expect the thresholds to be raised in this proportion. In actual fact so large an increase was never found, the maximum effect being a tenfold rise. The effects of instillation of two drops of 0.5-percent eserine and of 1.2-percent homatropine hydrobromide on threshold brightness were then studied, it being found that eserine has a comparable effect with that of D.F.P. On the other hand a slight reduction in the visual threshold occurred with homatropine as would be expected with a dilated pupil.

(e) *Vascular tone.* (See Figure 2).

* Threshold brightness in equivalent foot-candles. $\times 10^5$.

Subjects exposed to dosages of 100 mg. min./m³ and above generally showed hyperemia of the conjunctival vessels, the sign appearing some 48 to 72 hours after exposure with dosages up to 191 mg. min./m³ (although in one case it appeared within 24 hours). With a dosage of 250 mg. min./m³, the hyperemia was much more severe and was manifest within 24 hours of exposure. With this dosage, a marked congestive iritis developed in three of the volunteers, as evidenced by the presence of dilated iris vessels, and cells in the anterior chamber. This was present for one day only, and responded to instillations of homatropine.

The marked miosis of subjects exposed to D.F.P. vapor precluded a careful ophthalmoscopic study, except in the instances where the miosis was abolished with a mydriatic. No changes were noted.

(f) *Corneal changes.* No changes were observed under the slitlamp even with the highest dosages.

(g) *Subjective symptoms.* The subjective symptoms volunteered by the indi-

viduals exposed to the higher concentrations of vapor consisted in mistiness of vision, aching of the eyeballs, and difficulty in seeing in dim light. The symptoms began to clear up on the third day following exposure.

DISCUSSION

The results described in the earlier sections of this report speak for themselves. Several points emerging from this work will, however, bear comment. The most dangerous effect of D.F.P. vapor on the eye is clearly the congestive iritis caused by dosages of 250 mg. min./m³. Associated with the iris changes was a marked conjunctival hyperemia, both signs appearing some 24 hours after the exposure. With more moderate dosages of 100 to 200 mg. min./m³, conjunctival signs only were observed, and these appeared, with one exception, 48 hours after exposure. The cause of these delays is not easy to find—it may be that the continued accretion of unhydrolysed acetylcholine eventually causes sufficient stimulation of cholinergic dilator fibers to overcome the

normal constrictor tone of the eye vessels, but this is mere speculation.

The effects of the vapor on the accommodative apparatus were slight, suggesting merely the development of a greater than normal tension in the ciliary muscle during accommodation.

As one would expect, the diaphragm

effect of the miosis causes a rise in the threshold of night vision, similar in magnitude to the effects described in the literature.

SOME METHODS OF LID REPAIR AND RECONSTRUCTION

IV. TOTAL RECONSTRUCTION OF THE UPPER LID*

SIDNEY A. FOX, M.D.

New York

Trauma which destroys the entire upper lid and leaves the lower lid intact is a rare phenomenon. Spaeth¹ has labeled this type of case "the accident of an accident" and states, "No case has ever presented itself to the author in which the upper lid was alone involved and completely destroyed." This report is of interest, therefore, because it concerns just such an injury.

CASE REPORT

T. B. was wounded on April 13, 1945, while fighting in northern Luzon. He sustained a penetrating wound of the right upper lid and the right eyeball, fractures of the right orbital bones, and a laceration of the right frontal lobe of the brain. The following day the eye was enucleated, the upper part of the orbit exenterated

and the brain wound debrided. Recovery was uneventful, and the patient was returned to this country for further plastic surgery.

On admission to the hospital here, examination showed the upper lid to be completely absent. The whole socket except for the palpebral portion of the lower lid near the margin was lined with granulation tissue. The lower lid was intact but entropic. By some trick of fate the caruncle was spared. This was a welcome windfall as the final cosmetic result is always better when the caruncle is present (fig. 1). The repair was made as follows:

First Stage. A pedicle flap (1.5 cm. wide and 8 cm. long) was raised from the skin of the right forehead with the lower 4 mm. including the hair of the brow (fig. 2a). This was delayed for two weeks. Fourteen days later the skin edges around the upper orbit were freshened and the granulation tissue covering the

* From the Departments of Ophthalmology of the College of Medicine, New York University, and of Bellevue Hospital.

upper half of the socket carefully scraped away. The skin of the naso-orbital angle was undermined and mobilized. The pedicle flap from the brow was raised again, rotated down, and sutured above

Fig. 1 (Fox). Condition before operation showing total loss of the right upper lid. Socket is lined with granulation tissue. Note entropion of right lower lid and sparing of caruncle.

Fig. 2 (Fox). Diagram of procedure in first stage of repair. (a) A pedicle graft is raised from the forehead to include hair of brow at lower margin for the cilia line of the reconstructed lid. (b) After a delay of 14 days, the pedicle is raised again, rotated down, and sutured to the freshened skin edge below the brow.

and medially to the skin below the brow with interrupted sutures of 4-0 braided black silk (fig. 2b). The wound above the brow was closed with 4-0 plain catgut, subcuticular, and 4-0 black-silk skin sutures. The socket was stuffed with vaseline gauze and the graft pressed against the upper posterior socket wall to insure adequate blood supply. A firm supportive dressing with bandage was applied. The graft "took" well and the sutures were

Fig. 3 (Fox). Ten days later, before removal of the sutures. The graft has taken well.

removed on the 10th day after operation (fig. 3).

Second Stage. Six weeks later the graft, now obviously healthy and viable, was dissected away from the socket wall, and the socket itself was lined with a split skin graft taken from the inner aspect of the right arm. The method used here was described in a previous report published in the JOURNAL.² Figure 4 shows the reconstructed socket with a conformer in place.

Third Stage. Five weeks later the scar below the brow was excised and subcutaneous tissue resected to thin out the lid and give it a more normal appearance. (It should be remembered that brow skin is thicker than the skin of a normal lid). At the same time a free graft was taken from the left upper lid and planted in the bed thus prepared for it in the recon-

Fig. 4 (Fox). The graft is dissected away from the socket wall, and the socket is lined with a split skin graft. Conformer in place.

Fig. 5 (Fox). Lid graft is thinned out, and the free skin graft from the left upper lid is added to the right upper lid to widen it and to bring lid edge down parallel with lid of the other eye.

structed right lid. In this way the lid was widened and its edge brought down to approximately the same level as the left upper lid (fig. 5).

Five weeks later the entropion of the lower lid was corrected by exposing the tarso-orbital fascia and external canthal ligament and incising them sufficiently in the lower orbital quadrant to cause relaxation of the lid. This corrected the entropion too well (fig. 6) and subsequent tightening of the relaxed lower lid appeared necessary.

DISCUSSION

Many methods of repair are open to the surgeon in a case of this sort. These include, among others, the use of a tubed graft from the neck, rotated pedicles from the temple, cheek, and lower lid, and multiple free grafts of skin and cartilage. It is believed, however, that the method chosen here is the simplest available for a complicated case, for the following reasons:

1. There is comparatively little scarring as a result of the surgery, since most of the donor site is buried in the hair of the brow. For cosmetic reasons it is always best to have scars running parallel with the orbital margin whenever possible; a tubed graft or temporal pedicle would therefore have been more conspicuous.

2. The blood supply, and therefore the viability of the graft, is more certain with a pedicle than with a free graft, especially if delayed.

3. Since brow skin is at least as thick as the whole lid, the single layer was enough. Indeed, this single layer had to be thinned out to make the repaired lid conform to the other upper lid.

4. In a case of this sort there is no question of restoring function because there has been too much destruction. The reconstructed lid is immobile no matter what method is used. The aim of surgery here can only be cosmetic restoration, and the result is just about as good (or bad) as can be obtained with any other technique.

5. Because it is the simplest procedure technically, it is preferable.

In cases in which there is so much destruction, the question always arises as to whether the result is worth the effort. Some surgeons of long experience, whose opinions are valuable, feel that total lid reconstructions are never justified, because the patient is so often dissatisfied with the final result. Certainly patients should be warned before operation that one cannot reconstruct a complete lid to match the normal lid in every respect. One

Fig. 6 (Fox). Prosthesis in place after correction of entropion of right lower lid. "Stary" appearance is due to the sclera showing between the lower lid and limbus. This requires further correction.

must expect and be satisfied with a good deal less than perfection. If one succeeds in reconstructing a lid which is presentable and not conspicuous, the result is adequate.

In this case, lid and socket reconstruction made retention of a prosthesis possible and the patient was not condemned to wearing a patch for the rest of his life. The lid, although far from perfect, was sufficiently presentable so that the patient

was content and did not clamor for more surgery. He was even reluctant to have the lower lid pulled up for fear of "spoiling" the result.

SUMMARY

A method of total upper lid reconstruction by the combined use of a rotated pedicle and free graft is presented.

TECHNICAL METHODS FOR THE 1/2,000 FIELD*

MAX CHAMLIN, M.D.
New York

The study of the central field on the tangent screen is of great importance in ophthalmology and neurology. In those conditions where the field changes are marked, they are easily elicited with large visual angles and the technique is not very complicated. Thus, in marked papilledema the enlargement of the blind spot may easily be mapped out with a 10-mm. white test object at two meters. Also in cases of complete hemianopia, where the scotomatous areas are very dense, sufficient information may be elicited even by confrontation. However, in working with a large neurologic and neurosurgical staff one sees many cases with either minimal or questionable visual-field changes.

In such cases, more accurate information can be obtained by using a very small visual angle, such as the 1-mm. white test

object at 2,000 mm. The visual angle subtended by this combination is 1.72 minutes and is one of the smallest visual angles that is still compatible with practical clinical use. Because of the small size of this angle, this test must be reserved for patients with good enough vision to see the test object in a reasonably fair-sized portion of the field.

This small visual angle is especially useful in diagnosing cases of early lesions in which the 5/330 or 1/330 fields will show little or no defect. In such cases, the 1/2,000 test will bring out minimal changes. Thus, in early chiasmal interference, one may get a definite upper temporal slant with a 1/2,000 test, and little to no change with the 1/330 test on the perimeter. Many such cases are illustrated by Traquair.¹ In order to demonstrate this point, two cases have been selected from the neurosurgical service of Montefiore Hospital.

* This work was done in the Ophthalmological Laboratories of Montefiore Hospital, and was aided by the William L. Hernstadt Fund.

CASE REPORTS

Figure 1A shows the visual fields in a case of pituitary adenoma with chiasmal interference. The right eye shows only a slight peripheral, relative defect, temporally, for 1/330 white. The 1/2,000 test, however, shows almost complete loss of the upper temporal quadrant and beginning loss of the lower temporal quadrant.

Figure 1B demonstrates a case where the peripheral fields for 2/330 were normal, while the 1/2,000 test showed a definite bitemporal hemianopia. The latter case had very dense bitemporal, paracen-

tral scotomas preoperatively and a reduction in vision in the right eye to 6/200. X-ray studies showed an enlarged sella turcica. One week after the removal of a craniopharyngioma by Dr. Davidoff, vision returned to 20/20. At this time the peripheral field for 2/330 white was normal in both eyes while the 1/2,000 test still brought out the bitemporal defect (fig. 1B).

In some cases, the actual existence of a tumor was suggested by using a small visual angle when it was missed with a larger one. To quote Traquair, "In clinical work, the examination with 1/2,000

white is one of the most important tests and is indispensable. To omit the 1/2,000 white test is comparable to examining the central vision with a chart which has no line below 6/12ths."¹

Therefore, the study of the visual field with the 1-mm. white at 2,000 mm. is important in bringing out early or minimal defects in the visual pathways. However, the use of this small visual angle presents many technical difficulties, some of which will now be discussed.

Fig. 1 (Chamlin). (A) Case of pituitary adenoma. Right field for 1/330 white shows only relative defect in upper temporal field, while 1/2,000 test shows almost complete loss of upper temporal quadrant and beginning loss of lower temporal quadrant. (B) Case of craniopharyngioma one week after removal. The fields for 2/300 white show no changes but the fields for 1/2,000 white show a very sharply defined bitemporal hemianopia.

TECHNICAL DIFFICULTIES

PATIENT

One must be careful in selecting the proper type of patient for this test. It is easiest to do this test if the patient has good visual acuity and becomes more difficult with impairment of central vision. The patient must show evidence of understanding the test fully. Certainly, a patient whose mentality is dulled by intracranial lesions or preoperative medication is not fit for this test. He must be intelligent enough and dependable enough to distinguish the small white-headed target from any distraction and he must understand fully the need for constant fixation. It takes but a fleeting, almost imperceptible shift of the eye to look at the moving test object instead of the fixation point, thereby giving erroneous readings.

TECHNIQUE

Before starting the test, the test object and carrier are shown to the patient at close range, and it is explained to him that he must recognize the test object and not the adjacent parts of the carrier. The shaft of the Berens pin or the wire of the Evans bead must be pointed out to the patient so that he does not confuse them with the tiny test object.

The patient is made comfortable with a head and chin rest and one eye is carefully covered. The head and chin rest should be adjusted to the level of the patient's face so that he will not have to bend his head forward or backward. Excess inclination of this nature may give erroneous readings in the upper and lower fields. The patient should wear his distance correction, especially when visual acuity is poor without it. With glasses, care must be taken that neither the frame nor bifocal segment interferes with the field. If necessary, the lenses may be replaced with a large trial-case frame and lens.

It is best to start by using a large test object, such as 10 mm., then 3 mm., and finally 1 mm. In this way, one gradually teaches the patient the general idea of the test. Before recording the readings with the 1-mm. test object, it is well to take several practice readings. Several constant readings must be obtained in a single meridian before considering the patient's responses as reliable.

The field is explored along each of the various meridians. At Montefiore Hospital, the 2-m. screen is marked off in 22.5-degree meridians. The test object is moved toward the center along each of these meridians. The movement should be steady and not too slow. However, it must be slow enough so that the examiner can stop within about $\frac{1}{2}$ cm. from the point where the patient calls the test object as visible. Moving more rapidly may lead to errors. On the other hand, if the movement is much slower, nonexistent scotomas may be falsely recorded. This is so, because a small stimulus such as this one, when viewed indirectly in the periphery of a field for a short period of time, will disappear from view unless it is moved continually so as to stimulate fresh retinal receptor units.² Thus, if we move very slowly, the patient may say "I see it, but now it seems to be gone." Of course, one must be careful to differentiate such errors in technique from true scotomas. The area should again be explored with slightly faster motion, and the patient must tell whether or not the white object disappeared for a short distance.

There is no need for using any zigzag motion. This type of motion is unscientific in a test such as this one and in general perimetry, as well. The zigzagging gives the over-all effect of a larger test object and subtends, therefore, a larger visual angle. Such an error would give a larger field and nullify the accuracy of this test. Furthermore, in zigzagging, the

exact point at which the patient sights the object becomes less definite and, therefore, the findings are less exact.

The black-headed pins are used to mark the points at which the white object is seen. The pins are all dipped in flat black paint to avoid bright highlights. A better method of recording is to dictate to a recording secretary the readings for the various meridians and thus avoid the use of the pins entirely. If any peripheral indentations are mapped out, these abnormal readings must be checked. Furthermore, the immediate surrounding field should be explored so that one or two intermediate readings are made between the 22.5-degree markings. If a small peripheral contracture does not depend on a single reading, the interpretation will be more dependable.

TEST OBJECTS

A spherical test object has been found more satisfactory than a flat one. The visual angle is so small, and consequently taxes the patient's peripheral vision to such an extent, that a flat test object, if only slightly tilted, would introduce a large error. The test object must be clean and perfectly white. Since the Berens test objects are easily washable, they are satisfactory in this respect. However, the shaft of the pin has a thin, smooth layer of dark paint and, if the test object is used on a carrier that exposes this shaft, a brilliant highlight is thrown off which makes it quite difficult for the patient to distinguish the shaft from the tiny white bead in the peripheral field at 2,000 mm. When the shaft of the Berens pin is exposed, it is best to cover it with a coat of flat black paint, such as is used in photography. Apply the paint in a thick and irregular layer so that the surface will reflect less light.

TEST-OBJECT CARRIERS

The test-object carriers provided with a Berens set are two in number and are made of metal rods about 3 mm. in diameter. The many test objects are interchangeable. The end of the rod is rounded and contains a groove into which the shaft of the pin fits. The test-object carrier has a highly reflecting surface, thus giving an attractive highlight, particularly at the carrying end of the rod. This highlight is very distracting. In addition, the constant changing of test objects mars the paint and exposes the shiny metallic surface underneath which, of course, makes the carrier useless until repainted. When using these carriers, I cover them with the same kind of flat black paint I use on the pin shaft. If 3-mm. or 5-mm. test objects are being used, these difficulties are less important, but with a 1-mm. test object, they are of great significance. No matter how carefully the metal carriers are painted, they still give a more distinct reflection of light than a painted wooden surface of similar size and shape.

Another difficulty arises in a busy perimetry laboratory where one uses only one or two carriers with several different sizes of test objects. The holder and the shaft of the pin lose their paint rapidly and need frequent replacement. Even if the paint does not come off, the finish becomes undesirably shiny from constant handling. Then, too, when put to constant use, the small white head is easily broken off and is frequently soiled.

For these reasons I use test objects which are permanently mounted in separate carriers made of wooden carpenters' dowels about 3 mm. in diameter. These dowels are very inexpensive and come in lengths of 3 or 4 feet. Each dowel can be broken down into 3 or 4 carriers about 12 inches in length. Since they are thin and flexible, a vibratory motion is trans-

mitted to the test object if they are longer than 12 inches. The vibration is minimized, if one touches the tangent screen with the test object, but this is undesirable because the test object will be soiled, and the tiny bead can easily become enmeshed in the superficial fibers of the flannel.

The dowels are dipped into flat black paint. The shaft of the Berens pin is repainted and is then inserted into one end of the painted wooden dowel. To insert the pin, grasp the shaft with a hemostat near its point and force it into the center at one end of the wooden dowel, sinking it 3 mm. into the wood. If it is sunk less deeply, it may fall out. If it is forced farther into the dowel, the wood is apt to split.

Fig. 2B (Chamlin). Same cabinet as in Figure 2A with doors opened wide showing test-object carriers individually placed and standing upright in the holes in the wooden blocks fastened to bottom of cabinet and its doors. The switch to the light in the cabinet is underneath the box.

Fig. 2A (Chamlin). Wooden cabinet with glass doors shown closed and attached to wall.

After this test object has been attached to its permanent carrier, we try not to touch it or the adjacent parts of the carrier again. A photograph of such a carrier with the 1-mm test object on the Berens pin is shown in Figure 3D. If the pin-head should need cleaning, it can easily be washed with a tiny wet swab and wiped with a dry one.

A 3-mm. dowel is suitable for test objects up to 5 mm. but it is too thin to carry the weight of heavier test objects. When the objects are 10 mm. or more, employ a 6-mm. dowel. (The width of the carrier is no longer as important as it is with the smaller test objects.) These heavier

dowels and pin shafts are painted in the same way as the lighter ones, although the finish no longer plays the distracting role that it did with the 1-mm test object.

Heavier test objects are permanently fastened to individual wooden handles to avoid repeated handling of the test object, the pin shaft, and the carrier. By reducing handling, breakage and soiling are minimized.

All of these test objects permanently affixed to their carriers, are kept in a glass-enclosed wall cabinet (fig. 2A). Along the bottom of this cabinet, which is 6-inch deep, there is a block of wood with small holes bored in it, slightly wider than

Fig. 3 (Chamlin). (A) Large flannel-covered test-object carrier with 1-mm. test object. (B) Similar test-object carrier but much smaller for use with perimeter. (C) Flannel-covered steel carrier with white test object welded to steel. This is a 2.5-mm. test object. (D) Wooden dowel with Berens pin attached, dowel and shaft of pin being painted matt black. Test object is 1.0-mm. white.

(*Author's note.* Due to the tiny size of the 1-mm. test object, it is not visible in the above photograph. The 1-mm. test object is found in approximately the center of each of the paddle-shaped carriers A and B, also at the end of the shaft of the pin in D. The larger white test object at the end of carrier C is just about visible.)

the diameter of the dowels and 1-inch apart. All the carriers are inserted in this wooden block, with the test objects upward. The two doors closing off the front of the cabinet have a deep frame with a similar block of wood along their lower borders. Thus, when both doors of the cabinet are open (fig. 2B), the entire set of test objects can be checked at a glance, and any one of them can be removed or replaced with ease and without unnecessary handling.

In addition to making the test objects more lasting, the individual handles permit one to use them in rapid succession. For instance, in studying central fields, I frequently use the 1-mm. white, 2-mm.

red, and 5-mm. red one after another. If I am not sure that there is diminished vision in an area (that is, a relative scotoma), I can use "rapid comparison." By this, I mean a rapid comparison of vision in the questionable area with that in an area in which the patient professes to have good vision. If this vision is not brought out well with 1-mm. white, it may be brought out with 5-mm. red or 3-mm. red, and it is an advantage to have all these test objects available for rapid use.

An improvement on the combination of the painted wooden handle and the Berens pin would be plastic test objects permanently affixed to plastic carriers, the whole unit being in one piece. The handles of the set I plan to have made are to be of black, unpolished plastic, tapered at the end to which the plastic spherical test object is to be permanently affixed. Such a complete plastic set will eliminate the need for painting and will do away with the occasional breaking off or falling out of the pins from the dowels. Such equipment can easily be cleaned with a damp cloth without the danger of dislocating the pin, as in the wooden holder, and the colors will be permanent.

I have devised several other types of test-object carriers based on the principle that the carrier should simulate the background. The frame is made with flat, thin steel such as is used for stays in women's girdles. The shaft of the Berens pin is soldered to the end of the steel, and the presenting surface of the steel is covered with a length of the same felt or flannel that was used in making the tangent screen. The steel should be no more than $\frac{1}{4}$ to $\frac{1}{2}$ inch in width, so that the carrier, when overlapped by the material, is no wider than $\frac{1}{2}$ to $\frac{3}{4}$ inch. A carrier of this width is preferable to a narrower one because the wider piece of flannel, with edges more distinctly separated, is less

distracting. It is also easier to keep a wider carrier more nearly parallel to the plane of the screen, thus avoiding shadow. In cutting the edges of the felt, it is well to bevel them so that the bevelled edges will face the screen and not the patient. This is worth while doing because the bevelled edges stand out from the smooth surface of the tangent screen.

The pin is soldered so that only about $\frac{1}{8}$ -inch of shaft near the head projects beyond the end of the steel blade and is not covered by the felt. Dull black thread, such as Clark's black darning thread, is used to sew this felt to the steel. No stitches should appear on the presenting surface. The small $\frac{1}{8}$ -inch neck of shaft, between the end of the steel and the pin-head is covered by winding this thread around it. A flat surface is better than a rounded one such as the wooden dowel has, because a flat surface is less likely to give off a highlight. This test object is shown in Figure 3C. These test objects are also kept in an upright position so that the presenting surface and test object do not touch anything when not in use.

Another test object carrier that I have made has its size increased sufficiently to permit the object to be completely surrounded by the exact felt as was used for the screen. The frame for this carrier is fashioned from a sturdy steel wire, about $\frac{1}{8}$ inch in diameter. This wire is shaped into an oval about 6-inches wide and 9-inches long, with a handle about 5-inches long. A piece of the tangent-screen felt is stretched tautly over it. All of the stitching appears on the nonpresenting surface. The handle is also covered with the same felt. This carrier resembles a large ping-pong paddle.

The 1-mm. white pin is now grasped with a hemostat at the shaft adjacent to the head, and the remaining length of the shaft is bent until it is at right angles to the smaller portion between the hemostat

blades. The pin now looks like the letter "L" with the test object at the end of the shorter limb. The point of the shaft is now plunged through the center of the felt carrier about four inches from its rounded end, and, at the bend, turned at right angles so that the test object presents without any shaft showing, the short neck of the shaft going through the felt at right angles to the plane of the felt. The long end of the shaft now lies on the nonpresenting surface of the felt, and the point is engaged in the superficial fibers of the felt without going through it, and the test object is ready for use. This paddle-shaped test object is shown in Figure 3A.

Before using this test object, tell the patient that he will see a large black surface approaching and that at a certain point, a little white head will appear through the center. By having the test object completely surrounded with black felt for at least 3 or 4 inches in all directions, perfect contrast without interference is achieved. The patient can also recognize the test object more accurately because he knows where the object will appear and keeps his attention there, even though central fixation is well maintained. This gives a more accurate measurement of the field.

The carrier is moved slowly toward the point of fixation and, when the patient makes out the tiny white test object, the carrier is held in position and, with his other hand, the operator holds a black-headed pin over the white test object. The carrier is then withdrawn, and the black-headed pin is pushed into the screen.

The author has found this paddle type of carrier quite satisfactory in mapping out the 1/2,000 field. However, it is unsuitable for use within 2 or 3 degrees of the fixation point, since the surrounding carrier overlaps the fixation point at these limits.

INTERPRETATION OF FINDINGS

The normal isopter for 1/2,000 white in good illumination is reported differently by various observers, as shown in Table 1. Figures for this table are taken from Traquair.³

One must remember that this visual angle is very small and undoubtedly differs with various lighting backgrounds, reflections from test objects, types of carrier, technique of examination, and so forth. Considering all of these factors, it is not at all surprising that there are discrepancies in the findings of these observers. I believe that each ophthalmologist should observe the 1/2,000 field for a small series of normal subjects on his own screen in order to see which of the reported isopters is closest to the average isopter he has found on his own screen.

the test object temporal to the blind spot—usually over a narrow zone of 3 or 4 degrees. Therefore, this area must be explored carefully. In cases of papilledema, in which the blind spot extends as far as the 21- or 22-degree meridian with a 5- or 10-mm. white test object, there may be some additional pericaecal scotoma for 1/2,000 white, thus bringing the caecal area out perhaps to the 25- or 30-degree meridian. This would cause breaking through to the periphery for 1/2,000 white, thereby interfering with the 1/2,000 test in the sense that one might get the impression of a temporal slant; whereas, the depression is really due to the enlarged blind spot.

SUMMARY

1. The importance of the 1/2,000

TABLE 1

NORMAL ISOPTER FOR THE 1/2000 FIELD AS REPORTED BY VARIOUS OBSERVERS

Observer	Angle In	Object in mm.	Distance in mm.	Field in Degrees			
				Out	Down	In	Up
Walker	1.72	1.2	2,500	20	18	17	17
Sinclair	1.72	1.0	2,000	26	25	26	24
Hefftner	1.72	1.0	2,000	22	18	18	15

He should then use that reported isopter for the normal.

However, the exact extent of the 1/2,000 field is not really very important. Certainly, because of the discrepancies in different reported normals, little to no importance should be attached to small concentric contractures in this isopter in the absence of other perimetric evidence of interference with the visual pathways. Much more important is localized depression such as a definite temporal or bitemporal slant, homonymous hemianopia, and so forth.

A word of caution regarding the 1/2,000 field in the neighborhood of the blind spot is in order. In most cases, with good lighting, the normal patient will see

white isopter is emphasized as one of the more sensitive and practical tests in quantitative perimetry.

2. Some of the difficulties encountered in the use of this small visual angle are discussed.

3. Suggestions are made for the economical construction and care of individual, permanently fixed holders for small test objects, together with a cabinet for storing them.

4. A new type of carrier, based on a different principle, has been devised.

5. Suggestions are made for the interpretation of the findings for 1/2,000 white.

THE CLINICAL USE OF DI-ISOPROPYL FLUOROPHOSPHATE (D.F.P.)
IN CHRONIC GLAUCOMA*

WILLIAM G. MARR, M.D.

Baltimore, Maryland

Recently several articles on the treatment of glaucoma with di-isopropyl fluorophosphate (D.F.P.) have appeared in the literature. D.F.P. is a colorless oily liquid which hydrolyzes rapidly in aqueous solutions with the production of hydrofluoric and di-isopropyl phosphoric acids. Chemically, D.F.P. is unrelated to eserine. Koelle and Gilman have shown that D.F.P. is stable in peanut oil for at least one year when kept in a stoppered bottle at room temperature.¹ They also found no deterioration after autoclaving D.F.P. in peanut oil for one hour at 117°C. From pharmacologic studies on various laboratory animals, it has been learned that D.F.P. inactivates the enzyme cholinesterase. Because of its prolonged action and the rate at which enzyme cholinesterase activity reappears, it has been concluded that D.F.P. acts by irreversibly destroying cholinesterase.² When instilled in the eye, it therefore produces symptoms of marked parasympathetic activity which include miosis and contraction of the ciliary muscle.

ANIMAL EXPERIMENTS

Scholz found that, when sublethal or repeated doses of D.F.P. were instilled in the eyes of rabbits under ether anesthesia, tension rose simultaneously with the

pupillary constriction and did not begin to return toward normal until approximately 15 minutes later.³ Histologic examination of eyes removed with the tension elevated showed epithelial blisters on the ciliary processes, engorgement of the vessels, and coagulated protein in the anterior chamber. Scholz and Wallen, however, found that normal human eyes exposed to D.F.P. vapor showed a reduction in tension in all cases but one.⁴ The exception showed a slight rise in tension when measured at 10 minutes, but by three hours the tension had fallen below normal. Leopold and Comroe confirmed Scholz and Wallen's findings on normal eyes, but had no exceptions among their 12 cases.⁵ Leopold and Comroe demonstrated in human eyes that a 0.1-percent solution of D.F.P. was able to overcome the cycloplegic effect of 4-percent homatropine hydrobromide, and that a 0.2-percent solution of D.F.P. overcame 1-percent atropine sulfate.

CLINICAL EXPERIENCE

The clinical experience of Leopold and Comroe indicated that 0.05-, 0.1-, and 0.2-percent solutions of D.F.P. in oil were suitable for reducing the tension in cases of chronic simple glaucoma.⁶ They reported that solutions weaker than 0.05-percent failed to lower significantly the ocular tension in chronic glaucoma and that if a 0.2-percent solution was ineffective, in-

* From the Wilmer Ophthalmological Institute of the Johns Hopkins Hospital and University.

creasing the concentration of D.F.P. was of little value. Because of the prolonged action of D.F.P., Leopold and Comroe cautioned that the frequency of administration of the drug could be determined only by carefully observing the effect on the individual patient. The vast majority of their controlled cases received the drug between the limits of once weekly and twice daily. Most of the cases analyzed by Leopold and Comroe fell into the group classified as chronic simple glaucoma. They reported results on eyes in which pilocarpine and physostigmine had been used unsuccessfully and in which D.F.P. subsequently was used. Of the 52 glaucomatous eyes treated, the use of D.F.P. was considered successful in 36 eyes.

In another report McDonald compared the efficacy of D.F.P. with other miotics in 122 eyes with chronic simple glaucoma uncontrolled by the use of either pilocarpine or eserine.⁷ He reported that 57 percent of the eyes in his series were successfully controlled by D.F.P.

CRITERIA FOR STUDY

This study is based on the use of D.F.P. in 32 eyes with chronic glaucoma in which the glaucoma previously was uncontrolled by the use of such miotics as pilocarpine (1-percent or 2-percent), eserine ($\frac{1}{4}$ -percent), and furmethide (10-percent). The criteria for listing the cases as successfully treated with D.F.P. are the following: (1) The patient should be willing to use the drug sufficiently long to permit a minimum observation period of four months. (2) As a result of treatment, (a) the ocular tension as measured by a Schiøtz tonometer should be maintained at or below 30 mm. Hg; (b) the visual field should show no further loss; (c) vision should be maintained at pretreatment levels provided there is no other obvious reason for a reduction in vision.

Cases were considered unsuccessfully controlled when: (1) The patient was unwilling to continue the medication because of its induced ocular pain or visual symptoms. (2) During treatment, (a) the tension was not controlled at 30 mm. or less; (b) the visual field showed further loss; (c) the visual acuity was reduced.

In this series D.F.P. was used in 0.05- and 0.1-percent concentrations in peanut oil and the frequency of instillation varied from once every two days to twice daily. This is essentially the same concentration and frequency of instillation employed both by Leopold and Comroe and by McDonald.

TYPES OF GLAUCOMA

The types of glaucoma occurring among the 32 eyes in this series and the number successfully controlled with D.F.P. are shown in Table 1.

In these 32 eyes with chronic glaucoma uncontrolled by the more commonly used miotics, D.F.P. was successful in lowering the tension to below 30 mm. Hg (Schiøtz) and maintaining such a reduction for four months in only five eyes—an incidence of 16 percent success. In 27 eyes, the drug was ineffective. In 3 of the 27 failures, the drug was discontinued early because of pain which was so severe that the patients refused further treatment. In the remaining 24 eyes, D.F.P. did not control the tension within satisfactory limits for four months.

McDonald reported that approximately 57 percent of his total cases uncontrolled by previous miotic therapy were successfully controlled by D.F.P. However, he did not give the number of cases of chronic glaucoma alone in his series. His figures, therefore, cannot be accurately compared with the results here reported. Leopold and Comroe's article presented all the pertinent data on the individual cases. Therefore, a further analy-

sis can be made and a comparison with the results here reported is possible. In their series there were 52 eyes with chronic glaucoma which failed to respond to previous miotics. According to their criteria, D.F.P. was successful in 36 eyes and unsuccessful in 16 eyes. When the results of treatment of these 52 eyes are analyzed, using the same criteria which were employed in evaluating the series here reported, there are only 39 eyes which meet the criteria of period of observation and results of treatment. These 39 eyes include 23 apparent successes and their 16 failures. However 8 of the 23 apparent successes do not meet our requirement that the patient be willing to continue the medication. Patients represented by 8 eyes were unwilling to continue the D.F.P. because of either severe pain, blurring of vision, or both. Thus only 15 eyes out of a total of 39, or 38 percent of the chronic cases reported in Leopold and Comroe's article could be classed as successes under the criteria laid down in this paper. In their series it would appear from the available data that the most which could be expected by the use of D.F.P. in chronic glaucoma uncontrolled by the more commonly employed miotics would be control in one of every three cases for a minimum period of four months. The small series here reported gives an even less optimistic view of the situation, only one in six cases being controlled for four months or longer.

COMPLICATIONS OF THERAPY

The complications of D.F.P. therapy which have been mentioned in the literature are: (1) The severe eye or brow ache which is especially common during the first few days of therapy. (2) The blurring of vision caused by ciliary spasm. (3) The occasional increase in tension which D.F.P. may produce.

The following complications occurred in the 32 eyes of our series. Four patients experienced so much pain that in three the therapy was discontinued, and in the fourth, morphine was required the first night to alleviate the pain. This patient was subsequently carried for several days without pain on D.F.P. One aphakic is included among the four which experienced severe pain. Two patients with aphakic eyes also experienced mild pain during the first three days of therapy which was not severe enough to make

TABLE I
TYPES OF GLAUCOMA OCCURRING IN 32
EYES OF THIS SERIES

Type of Glaucoma	No. of Eyes	No. Controlled by D.F.P.
Glaucoma Simplex	10 eyes	1
Glaucoma Secondary to Cataract Extraction	8 eyes	2
Glaucoma Secondary to Uveitis	4 eyes	0
Absolute Glaucoma	4 eyes	0
Chronic Congestive Glaucoma	4 eyes	0
Congenital Aniridia	2 eyes	2

the patient unwilling to use the medication.

Three patients with glaucoma simplex became so artificially myopic from ciliary spasm induced by D.F.P. that the resultant vision was unsatisfactory. For example, one of these patients had 20/20 corrected vision prior to the instillation of D.F.P. While receiving D.F.P. (1 drop of 0.05-percent solution, twice daily) in the left eye, her vision varied on different visits to the clinic from 20/50 to 20/100. A manifest refraction on a day in which the vision was 20/70 showed that a -2.5D. sph. lens was required to give 20/20 vision. Because of the variability of the ciliary spasm in this case,

the induced myopia could not be satisfactorily corrected by a permanent change in the spectacle lens. In three of the four eyes with chronic congestive glaucoma, the anterior chamber became more shallow after the use of D.F.P., without any reduction in tension. A reduction in depth of the anterior chamber was also noticed in several eyes with glaucoma simplex.

ADVANTAGES OF THERAPY

The advantages reported for D.F.P., when it satisfactorily controls the tension, are the convenient infrequency of administration and the absence of a local sensitivity reaction. The advantage of fewer daily instillations is somewhat offset by the pain which may occur and the temporary myopia which may result. One case treated with D.F.P. but not included in this series is of especial interest. In this patient, the use of D.F.P. apparently caused a ciliary spasm so severe that the resultant traction on the choroid and retina produced a retinal detachment.

REPORT OF A CASE

A 62-year-old white man, with moderate myopia corrected to 20/30 in both eyes, had glaucoma simplex, and the tension was satisfactorily controlled on pilocarpine (3 times daily) ordered by his local ophthalmologist. Because of the inconvenience of the mid-day dose, it was

decided to try D.F.P. Two drops of a 0.1-percent D.F.P. were placed in each eye and immediately following the instillation severe pain developed in both eyes and vision became blurred. These symptoms disappeared after 24 hours. The following morning (approximately 36 hours after the instillation of the D.F.P.) the patient noticed a grayish veil hanging down nasally in the visual field of the right eye. Metamorphopsia developed and the upper field became distorted. One month later when the pupil was dilated for the first time, the lower retina was found to be detached. The patient was then referred to the Wilmer Institute. On examination, a disinsertion of the retina in the lower temporal quadrant with detachment of the lower retina was found.

CONCLUSION

From our studies on chronic glaucoma, it would appear that when other miotics such as pilocarpine, eserine, and especially furmethide fail to control the tension, D.F.P. in the concentrations used has little chance of success. Furthermore, although D.F.P.* may be ineffectual, it is not always innocuous.

Johns Hopkins Hospital (5).

NOTES, CASES, INSTRUMENTS

METASTATIC FUSOSPIROCHETAL ABSCESS OF THE ORBIT*

L. L. TITCHE, M.D.

Tucson, Arizona

Metastatic abscess of the orbit is not uncommon and orbital abscess caused by *Borrelia vincentii* and *Fusiformis dentium* is not rare, but the combination of the two is an unusual occurrence. In most instances the latter condition is the result of the extension to the orbit of an infection of the maxillary sinus following a dental infection. Dunnington and Khorazo,³ in 1936, reported a survey of the literature and found only 13 cases of ocular infection due to *Borrelia vincentii* and *Fusiformis dentium*. Walker⁴ reported a case of abscess of the orbit and suppurative panophthalmitis produced by these organisms as the result of an infection of the maxillary sinus following the extraction of a tooth. Burch² reported a case of metastatic orbital infection from a staphylococcal pulmonary infection. Berens¹ stated that metastatic abscess of the orbit occasionally arises in infectious diseases, scarlet fever, chicken pox, and influenza, and from surgical operations for infections in other parts of the body, as pelvic cellulitis and uterine disease. Because of the rarity of the condition, it is believed that the following case is worth reporting.

CASE REPORT

R. M. C., a white man, aged 52 years, was admitted to this hospital on October 10, 1944, for the treatment of bronchi-

ectasis, severe, bilateral. The pulmonary condition was too extensive for surgery and his therapy consisted of postural drainage and frequent bronchoscopies with the insufflation of sulfonamides into the bronchial tree. Sputum examination yielded Gram-negative fusiform bacilli and spirilla on smear.

On January 14, 1946, he complained of pain in the right eye. Examination revealed slight puffiness of the right lower eyelid, but intraocular examination was negative. Heat was applied, and two days later the swelling had increased and it was noted that ocular motion was limited.

On January 16, 1946, an abscess on the outer aspect of the left arm was incised. Purulent material was found which had a very acrid odor and was rather viscous and gray in appearance. Smears of this material revealed many spirilla and Gram-negative fusiform bacilli, but there was no growth on culture. By the following day, there was marked swelling of the right lower eyelid and fluctuation could be felt. The conjunctiva was markedly injected and the globe was proptosed about 6 mm. and fixed. A 22-gauge needle was introduced in the area of fluctuation and pus was encountered at a depth of 3 cm. Aspiration yielded 4 cc. of thick, creamy, purulent material with a foul acrid odor. An incision was made along the needle to the abscess cavity and a drain inserted. Smears of this material were found to contain bipolar staining bacilli, Gram-positive cocci in chains, and spirilla. No growth was obtained on culture. The abscess was irrigated frequently with 20,000 units of penicillin in 2 cc. of normal saline and within a week had completely healed. The proptosis subsided rapidly, but some

* From the Veterans Administration Hospital. Published with the permission of the chief medical director, Veterans Administration, who assumes no responsibility for the opinions expressed or the conclusions drawn by the author.

limitation of motion of the globe persisted for several months.

On January 28, 1946, an abscess on the anteromedial aspect of the left thigh was incised with the finding of purulent material similar to that above. During this time a series of daily blood cultures for five days was reported as sterile after two weeks' incubation.

SUMMARY

A case of metastatic abscess of the orbit, accompanied by metastatic abscesses in other parts of the body due to *Borrelia vincentii* and *Fusiformis dentium* infection of bronchiectasis, has been reported.

Veterans Administration Hospital.

TECHNIQUE OF CATARACT OPERATION WITH THE ORAL-SUCTION CUPPING APPARATUS*

PEDRO FALCÃO, M.D.
Ribeirão Preto, Brazil

Intracapsular extraction of the lens by means of suction in operations for cataract is an already known and approved method. It is the purpose of this paper to present an improved cupping apparatus and the technique of its use in order to acquaint ophthalmologists with a method of cataract extraction which is at once simple and safe.

Although it is not the aim of this paper to discuss the various techniques of cataract extraction, it would be well to refer to some of the fundamental principles upon which all these techniques are based. Among these are: (1) Complete anesthesia and akinesia of the eye. (2) Corneoscleral sutures complete with a conjunctival flap. (3) Peripheral iridec-

tomy. (4) Intracapsular extraction of the lens.

It is the purpose of this paper to demonstrate that, no matter what kind of cataract is being operated, the cupping apparatus under discussion is the ideal instrument to use to extract the lens itself. Simple to apply, its handling is easy and delicate. Since there is automatic control of vacuum, the surgeon is able to do his task with a feeling of security. Assuring a precise apprehension at a chosen point, it permits an almost nontraumatic rupture of the zonule. The nucleus turns within its own capsule so that its posterior surface becomes the anterior one when passing through the corneoscleral incision.

DESCRIPTION OF APPARATUS

The apparatus is made up of four parts: (1) The nozzle (the cupping part, itself) which is made of chrome-plated metal. This concha-shaped nozzle is one of the principal innovations of the instrument. (2) A chrome-plated metal tubular body. (3) A tube made of rubber. (4) A mouthpiece.

* Report presented to the V. Brazilian Congress of Ophthalmology, Salvador, Brazil, 1945.

As its name implies, the mouthpiece (fig. 1, no. 1) is held in the mouth, between both lips, in such a manner that suction is produced by the mouth muscles only. In this manner, the vacuum is regulated. The mouthpiece, 22 mm. in length, is made of an acrylic material and is easily sterilized in steam (autoclave or

portion of the apparatus is strong but light so that it can be handled with ease and can be made to follow every movement of rotation with dexterity. The rubber tubing is fitted to one end. At the other end is a polished conic joint. The nozzle, maintained in position by a delicate thread, is attached to this conic joint.

Fig. 1 (Falcão). Cupping apparatus for cataract operations (top) ready for use, and its separate parts: 1, mouth piece; 2, tube; 3, body; 4, nozzle.

sterilizer). It cannot, however, be sterilized by certain solvents, such as chloroform, various organic acids, and so forth.

The rubber tube (fig. 1, no. 2) is able to withstand a pressure of 90 cm. Hg. Its average length is 40 cm.; its diameter, 1.5 mm.; its circumference, 3.5 mm. It is designed to link the mouthpiece with the body of the apparatus.

The body (fig. 1, no. 3) is a hollow, chrome-plated metal cylinder, 12.5 cm. in length. Its circumference is 8 mm. Simple in construction and like a pencil, the body

The body can be sterilized by steam or hot air, as well as by certain chemicals such as formalin.

The nozzle (fig. 1, no. 4) is a small and thin chrome-plated metal tube. At one end is the trunk which fits the conical joint of the body. As has been mentioned, a thin thread fixes the nozzle on the joint and makes the connection airtight. A careful test must be made to see that an airtight connection has been achieved.

At the other end of the nozzle is the concha which, when introduced into the

anterior chamber in juxtaposition with the anterior lens capsule, grasps the cataract. The nozzle can be sterilized with either steam or hot air.

Nozzles of two sizes accompany this apparatus. The smaller one (diameter, 2.4 mm., circumference, 3.4 mm., depth,

of its small size (its diameter is less than the length of the jaws of Arruga's capsule forceps), the concha has a large gripping capacity. The circular edge of the concha has no abrupt angles (fig. 1, no. 4). Its somewhat concave shape gives it an area of sufficient size to permit it

Fig. 2 (Falcão). Technique of grasping and extracting the lens with (A) the larger cupping apparatus and (B) the smaller cupping apparatus. (Author's note: In order to make the subject matter more clear, the above drawings do not keep the precise anatomic relation.)

1.7 mm.) is designed to extract the lens without turning it to 180 degrees. The larger nozzle has a diameter of 3.4 mm., a circumference of 4.6 mm., and a depth of 1.7 mm. It was designed for use in the operating of hypermature cataracts with large, hard nuclei. The technique of lens extraction with this nozzle is similar to that employed in the use of several well-known cupping apparatuses. A rotating movement of 180 degrees is used to extract the lens with the capsule and nucleus intact.

The innovation peculiar to these nozzles is the shape of the concha. In spite

to adhere no matter from what angle the manipulations are performed.

TECHNIQUE OF OPERATION

Although the management of the cupping apparatus is simple, its operation requires extreme care and delicacy. It is also essential that illumination be adequate and correct.

Use of smaller nozzle. Assemble the various parts of the apparatus and check to see that they are in perfect working order. With the eye under proper mydriasis, the cupping apparatus is introduced, preferably through the temporal side of

the wound. It is passed down over the iris close to the inferior edge of the lens, and the concha is gently applied to the anterior capsule.

When the proper moment for grasping the lens has arrived, vacuum is created by suction on the mouthpiece of the apparatus. The operator devotes his attention to rupturing the zonule and the hyaloid-capsular ligaments. He can increase or decrease the suction. The maneuver of detaching the lens is identical to that employed with forceps. All that is needed is to raise and gently withdraw the nozzle and lens. If necessary, a circular tenaculum or a stilet may be used below the place of zonular adherence to complete the rupture of the crystalline ligament.

Use of large nozzle. In general, the technique employed with the larger nozzle is the same. There must be sufficient mydriasis to permit the adjustment of the concha somewhat below the horizontal meridian of the lens. After the zonule has been ruptured, a movement of rotation is set up at the same time that the cupping apparatus is lifted and withdrawn. The nucleus and its capsule come out adhering to the concha.

It is important to remember that, during the use of the cupping apparatus, the power of adhesion is always increased when traction is exerted in a direction perpendicular to the plane at which the concha adheres to the surface.

DISCUSSION

Since the extraction of the lens has, throughout all the periods of cataract operation, been a most delicate and difficult problem, any technique which facilitates its removal and prevents accidents must be considered an improvement. My aim, therefore, has been to simplify to the utmost techniques already in existence. Mathieu, in 1866, and Hertz of

Vienna, at a later date, removed cataracts by suction, but their methods did not improve upon the then prevailing techniques.

As time went on, vacuum in the cupping apparatus was obtained by means of pneumatic pumps of various types. Evolution of the devices progressed from the pear of Stoewer through the more modern electrical machines of Barraquer and Castroviejo to the fountain pumps of Dimitri, Rochon-Duvigieand, Arruga, and so forth. Fisher, of Chicago, decided to insert a diverticulum in the connection tube between the pumping engine (1/6 h.p.) and the cupping apparatus itself. His diverticulum is of rubber and has a mouthpiece by means of which the vacuum is regulated. This does not, however, afford an entirely satisfactory means of regulation.

After giving fair trial to these various types of cupping apparatus, I concluded that to be truly satisfactory the apparatus should have these features: (1) Perfect vacuum, perfectly regulated. (2) A nozzle sufficiently small to permit insertion through half-dilated pupils. With the cooperation of Dr. Cintra do Prado, professor of physics at the Polytechnic School in São Paulo, and his assistants, experiments for improving existing apparatus were undertaken.

By means of the mercury vacuum meter, temperature 24°C., corrected pressure 700 gm., we calculated that the oral vacuum produced by the mouth muscles oscillates between 350 to 450 mm. The highest vacuum obtained was 635 mm., exactly the amount produced by the pump of Barraquer. This eliminated the criticism that orally produced vacuum would be insufficient to permit the proper application of the cupping apparatus.

The grasping power of the cupping apparatus does not, however, depend entirely upon the production of a vacuum.

Earlier failures did not depend upon the lack of sufficient suction power, alone. The structure of the nozzle by means of which the lens is grasped was also at fault. I felt that the area which would adhere to the crystalline lens could be increased, and that better adhesion could be achieved.

To substantiate this theory an interesting experiment was devised. A small ball made of thin rubber was filled with water and placed on a coin balance. The liquid tension inside of the ball was similar to that of a swelling cataract, and the ball was stout enough to support a traction force greater than any crystalline lens could endure without breaking up.

The nozzle of the cupping apparatus was adjusted to this ball, vacuum was created, the ball was drawn slowly and progressively toward the scale of the balance, and its weight in grams was noted at the precise moment of its liberation. Following this plan, the efficiency of a number of different types of cupping apparatuses, in which the suction pressure registered from 200 to 700 mm. Hg, was measured. The results showed that the only cupping apparatus approaching ours in efficiency was that of Barraquer and of Rochon-Duvigueand. The results for our apparatus showed:

	<i>Small Nozzle</i> (2.4 mm.)	<i>Large Nozzle</i> (3.4 mm.)
<i>Vacuum</i>		
700 mm.	60 gm.	95 gm.
400 mm.	35 gm.	55 gm.

After testing the same cupping apparatus several times, employing strong oral aspiration, we recorded these results:

Oral suction using small nozzle measured 45 gm.; using large nozzle, 85 gm.

Since the normal lens weighs between 0.20 and 0.30 gm., we concluded that our cupping apparatus was capable of lifting 200 to 400 times the weight of a normal lens. This would be more than the power needed to rupture the zonule and to extract the lens.

After the results of these preliminary experiments were corroborated by work done on the eyes of animals, we operated on 12 patients from the clinic with this apparatus. Eleven of these operations were successful. The 12th case, that of a boy, aged 16 years, failed because of the unbreakable resistance of Zinn's ligament.

SUMMARY

A cupping apparatus constructed on the principle of oral suction is presented. The mouth muscles are used to produce sufficient vacuum, and respiration is not disturbed. Between 350 and 450 mm. Hg pressure is required to extract the lens, and this amount of pressure can be regulated automatically. The apparatus is equipped with a smaller and a larger nozzle. Either size can be used with equal ease; the smaller is designed for extracting the lens without turning it to 180 degrees; the larger is to be used when a rotating movement of 180 degrees is required. The simplicity and security offered by the technique of this method of intracapsular cataract extraction recommend its use.

Rua Visconde de Inhaúma—59.

SOCIETY PROCEEDINGS

Edited by DONALD J. LYLE, M.D.

COLLEGE OF PHYSICIANS OF PHILADELPHIA

SECTION ON OPHTHALMOLOGY

December 19, 1946

DR. BURTON CHANCE, *chairman*

PATHOGENICITY OF DIPHTHEROIDS ISOLATED FROM HUMAN CONJUNCTIVA*

DR. CHARLES WEISS,[†] and MR. M. C. SHEVKY,[‡] presented this subject. Diphtheroids, resembling *C. xerose* and isolated from the human conjunctiva grow well in a menstruum of mucin. Similarly, when suspended in this medium and inoculated into the anterior chamber of the eyes of albino rabbits, cultures retain their viability for several days, although they are rapidly destroyed in salt solution.

Intraocular injections of rabbits with diphtheroids, suspended in saline, produce moderate inflammation of the ciliary process. When suspended in mucin, the reaction lasts longer, is much more severe, and is associated with an acute keratitis. The lesions usually regress spontaneously within 2 or 3 weeks.

When killed cultures of diphtheroids in saline produce mild inflammatory changes in the ciliary process which can be seen in histologic sections; none are visible grossly. In a menstruum of mucin, the inflammatory reaction is more severe.

*From the Laboratory for Ophthalmic Research, Mt. Zion Hospital, San Francisco, California. Aided by a grant from the Columbia Foundation.

[†] Present address: Laboratories of the Jewish Hospital, Philadelphia 41, Pennsylvania.

[‡] Now at the University of California, Department of Bacteriology.

Since mucin by itself is relatively innocuous, it is suggested on the basis of these studies and those of others that it protects bacteria from the digestive action of humoral and cellular proteolytic enzymes and other immunologic defense mechanisms. Living diphtheroids are thus permitted to grow and exert their pathogenic activity.

By means of the recently developed methods of Muller and Miller and Pappenheimer and Johnson, it was possible to demonstrate that when diphtheroids are grown in a medium of very low iron concentration, they yield a toxic filtrate which is injurious to the uvea and cornea but not to the skin or conjunctiva of albino rabbits.

Studies which had been planned on the specific chemotherapy and serotherapy of diphtheroids were interrupted because of the war emergency.

On the basis of these investigations, it may be concluded that diphtheroids which are present on the normal or the inflamed conjunctiva may be considered as potential pathogens which can exert serious injury when they find their way into the interior of the eye.

Discussion. Dr. Luther Kauffman: I wonder, from a practical point of view, in treating conditions involving the conjunctiva whether the proper procedure would be to get rid of the mucin. I am reminded of the solution of monohydrated sodium carbonate, which Dr. Lehrfeld presented before this section some years ago in his treatment of vernal conjunctivitis. It would also be interesting to ask Dr. Weiss if he knows whether other bacteria receive the same protective help from mucin as these diphtheroids do.

Dr. Burton Chance: The early death of diphtheroids reminds me of my own experience in the early days of my medical practice, when diphtheria was a frequent disease. For two winters I volunteered at the old Municipal Hospital. In one week, 275 sick persons were inspected. There were a good many patients there because the bacteriologist, who was at the summit of bacteriology at that time, had found what he believed to be the diphtheric organism in the conjunctiva and fauces. A few days after the children were admitted, another examination was made, with negative results, which created more than a headache, both on the outside and inside the hospital. The children were interested to know whether or not it had been true. The people outside were kicking because their children had been taken away from home and isolated. Having to have their own toothbrush and to carry out other hygienic measures were the sources of complaints from the children. Also, there were no signs of the old diphtheria of the conjunctival tissues that prevailed in earlier times. My teachers would refuse to accept a diagnosis of diphtheria unless there were actual structural and infiltration changes. Your statement concerning the evanescence of the diphtheroids, therefore, has reminded me of that somewhat confusing experience.

Dr. Charles Weiss, in closing, replied to the first question: Generally speaking, mucin on the inflamed conjunctiva is due to bacteria. Of course, it may also be due to chemical irritants. It seems reasonable, on the basis of our work, to remove it.

I mentioned in the course of my presentation that the virulence of a number of other bacteria is increased by mucin. Among them are: the meningococcus, the gonococcus, *V. cholerae*, and also the virus of influenza.

EXPERIENCE IN TESTING THOSE WITH DEFECTIVE COLOR SENSE

DR. BURTON CHANCE stated that from his earliest years, even in his first school days, he became aware that some persons were color blind, and ever since then he has been interested in color. In recent years, that visual defect has become the subject of so much investigation that he has ventured to tell something of his own interest in it and to express his beliefs concerning it.

The perception of color by human beings is an intellectual process involving psychologic and physiologic factors operating with the effects of light upon the chemical elements in the retina. The average person is able to distinguish all seven colors in the visible spectrum, and it is not improbable that animals and birds perceive beyond what mankind can define. There occasionally is found one whose appreciable "spectrum" is shortened at either end, if not both ends. For others, the ends are only more or less indistinct. In certain persons, however, the extent of the spectrum is not present; hence the appellation—color blind. A better and more kindly term is achromatopsia. Men more than women are affected. It is hereditarily transmitted from one generation to another through females who might not themselves be known to be affected. In pure cases, the eyes are not visibly changed structurally. Disease of the retinobulbar may be accompanied by defect in color perception. The color manifestations of the defect are, however, not usually comparable to those of the congenitally deficient. A singular anomaly is shown by those who have a unilateral deficiency; that is, complete perception is possible with one eye.

The measurement of color perception has aroused serious consideration in the

arts and in transportation, as well as in the definition of members of the military forces. Many notable persons in history have been found deficient and, since it was a pronounced defect in the case of John Dalton, the famous English physicist, it has been given deep study and various schemes for testing have been devised.

Such tests have been composed of wools, colored charts, and colored lights which are compared or matched with certain standard colors selected after prolonged investigation. In practice, red and green have been the colors most frequently found deficient; hence, these colors have been adopted as the basic standard for all tests.

Color perception is an unsolved mystery. Many theories have been proposed, but none solves all the problems, although the advocates of each theory defend their hypotheses violently. Thus far, the theory offered by Thomas Young and later similarly arrived at by Helmholtz has the least uncertainties. According to Young and Helmholtz, each color excites its own system of nervous conduction to the brain's perceptions.

Being a congenital defect, color blindness cannot be cured or even reduced—all schemes proposed are only false promises. Individuals can be trained to distinguish more fully one color from another; yet, when standard lights or plates are modified, as by foggy atmosphere or color dilutions, the natural defects become manifest.

All subjects do not have identical defects—some lack one or two; others more, even all seven colors. Observers have, therefore, classified them according to the number. Some persons showing only a lessening of the color strength are classed as anomalous of those color classes. Increasing attention to the "anom-

alous" is being carried on today. Those persons to whom all colored objects appear to be black are spoken of as the monochromatic. Despite all the interest shown in the past 50 years, no new fundamental facts relating to the problem have been solved; their solution rests with the photochemistry of the retina.

Discussion. Dr. George F. J. Kelly: It is my impression that you spoke of several cases of normal color perception in one eye and abnormal color perception in the fellow eye. Was there any evidence of pathologic changes in the fundi of the abnormal eyes?

Dr. P. Robb McDonald: I have been interested in Dr. Chance's paper because, for part of the time that I was in the Service, I was working with those who were engaged in developing tests for color vision.

As Dr. Chance has said this is a rather confusing subject. I notice that he also stuck to the term "color defective." This is a much more appropriate term than color blind. There are a lot of people who have defective color vision but who are by no means color blind.

In setting up tests for color vision, there were certain facts that had to be known. They were essentially:

1. A "job analysis" to determine what color discriminations were actually required of pilots, bombardiers, air crew, and so forth.

2. An evaluation of the tests of color vision that were available.

3. The development of new tests.

4. The reproducibility, reliability, and validation of the tests that were adopted.

The problem of landing a plane in the daytime was not too difficult because usually other clues than color were employed to determine whether one was about to land on tilled or flat surfaces. At night the problem was more difficult. The

runway markers might be colored lights of low intensity, the landing might be made with glide-path indicators, or the only communication between the tower and the pilot might be by a directional light such as the "biscuit gun." Those who worked about the airplane also had to make certain color discriminations. The wiring was usually coded by color, the various fuses had color codes, and so forth.

What everyone wanted was a quantitative test of color vision. One of the closest approaches to this was a lantern developed by Dr. Louise L. Sloan. The test was modified from one developed by the R.C.A.F., which in turn was a modification of the Williams lantern. The test was called a color-threshold test, and consisted of presenting eight different colored lights at eight different intensities of illumination. The minimum intensity was that at which most normal individuals called the color correctly. A score of 62 to 64 was considered normal.

We were fortunate in having a considerable number of color-defective individuals at Randolph Field, and Dr. Sloan was able to test them on the various tests of color vision. In all, about six tests were used—the Ishihara, the American Optical Company's pseudo-isochromatic plates, an abridged edition of the same, the Rabkin polychromatic plates, an anomalscope test, and the color-threshold test. Several other tests were employed at one time or another. Either before or after this battery of tests, the individuals were given "practical" tests; that is, the identification of colored flares actually fired from an airplane, the identification of colored signal lights, the identification of colored codes on wires, and so forth.

On the basis of these tests, the color-threshold tester was the closest approximation to a quantitative test. I think that

in the future we may have two types of color-vision tests. One that we can do in the office to determine whether an individual is normal or not, and one which the military can use to determine whether a soldier is color safe or not.

Dr. Burton Chance, in closing: In the several instances where I have seen perfection in one eye but defective perception in the other, there were no visible changes in the fundus. It is more than likely that if it be true that the perception of color is generated by the action of light on the retinal pigment, there was something constitutionally lacking in such eyes as gave rise to the defect. Therefore, in this consideration, I would not class a unilateral case presenting changes in the fundus as a true case of color blindness.

I wish to thank you, Dr. McDonald, for telling us something of what was done in the last Army. I regret that I was afforded no opportunity to witness such studies personally.

DR. HOWARD F. HILL, *presiding*

COMPLICATIONS ENCOUNTERED IN KERATOPLASTY

DR. R. TOWNLEY PATON of New York introduced his subject with a discussion of essential preliminary considerations. Only homotransplants or autotransplants have proved successful. Of the four types of corneal transplants—(1) total corneal transplantation; (2) total lamella transplantation; (3) partial lamella transplantation; and (4) partial penetrating corneal transplantation—the last method

gives the best results in specially selected cases. He classified cases for operation as: (1) For cosmetic improvement alone; (2) favorable for improvement of vision; (3) partially favorable for improvement of vision; (4) unfavorable for improvement of vision; (5) for treatment of descemetocoele.

The most favorable cases are those in which there is a nebulous type of opacity, quite central, and in an otherwise normal eye. There must be no active corneal disease present, or active infection of the conjunctiva, sclera, or uveal tract. There must be no increased intraocular pressure and no vascularization of the cornea. Blood staining of the cornea and conical cornea usually indicate favorable cases. The partially favorable cases are those in which there is some vascularization present and in which the opacity is dense with little clear cornea surrounding it, cases of adherent leukoma, shallow anterior chamber, and some cases of corneal dystrophy. Aphakic eyes, as a rule, do not do well, but some good results have been obtained. Cases in which the scarring is not too dense but in which there is a marked reduction in the corneal reflex should be given a guarded prognosis. Unfavorable cases include most forms of dystrophy, most forms of lipid and calcareous dystrophy, trachoma where there is a dense vascularization, lime burns and powder burns, hyperirritable eyes in which the cornea is densely and completely scarred as the result of acid and gas burns, pemphigus, and cases of severe symblepharon.

Dr. Paton stressed that, no surgeon, no matter how well qualified, should attempt this operation before experimenting on animals and dead human eyes and refreshing his memory on the anatomy and physiology of the cornea.

The selection, obtaining, and preserving of donor material was briefly discussed. Types of operation are: (1) Use

of stencils; (2) double-bladed knife or square window; (3) the trephine or round window. The technique of these procedures was summarized. He feels that the trephine method is the most advantageous because: (1) Better cosmetic result is obtained. (2) It is easier to complete the cutting of the window with scissors. (3) There is less danger of dulling the edge of the instrument in sterilization because of the adjustable collar. (4) An outline is made more easily with no danger of perforation because of the adjustable stop. (5) The donor window can be cut completely, thus eliminating the use of scissors.

Dr. Paton also prefers to use two sutures of different color because: (1) This gives increased ease of tightening; (2) more even distribution of pressure can be obtained, especially when there is a tendency toward overriding of one side of graft; (3) there is less danger of complication if one suture becomes frayed or is accidentally cut; (4) if further reinforcement is desired before the ends are cut, the suture can be anchored diagonally opposite in the episclera near the limbus or in the corneal tissue at the limbus.

Several points of consideration at time of operation were noted. Eyes with nystagmus may be operated upon, but the results are not good, as these eyes are invariably amblyopic. Cataract extraction and squint operations should be done after and not before the transplant has been performed. In aphakic eyes, the sword knife or the Filatov prophylactic spatula should be used to hold back vitreous during operative procedures. Operations on children before the age of 8 or 9 years or on glaucomatous eyes, should be avoided.

The postoperative complications may be grouped as follows: (1) Those produced by poor technique and unsatis-

factory instruments may result in: (a) edema of graft, (b) poor fit which may also cause the anterior chamber to collapse, (c) anterior synechias which often cause clouding of the graft. (2) Those that result from poor choice of patient. (3) Poor donor material and vascularization. (4) Unforeseen complications, such as infections and stitch abscess. (5) Cataract. (6) Glaucoma.

In summarizing the results, Dr. Paton said that in favorable cases visual improvement from 20/200 to 20/15 may be expected, but the latter acuity is rarer, occurring in about 2 percent of cases. Most cases require, postoperatively, a high minus correction with a high cylinder correction. Conical cornea cases give favorable results, but should not be operated upon unless contact glasses are not well tolerated, or if visual improvement cannot be obtained further than 20/200. A large graft should be used in these cases whenever possible.

Discussion. Dr. Brendan Leahey in discussing Dr. Paton's paper, said that much more keratoplasty has been done in New York than in Boston, and that, in the 8½ years since he obtained his first clear graft, his own series had risen only to 40 cases. Despite this, however, he felt sure he could at least hold his own with Dr. Paton when it comes to complications. He had hoped that Dr. Paton would say more about the removal of blood vessels, as that has been one of his worst problems in getting cases ready for operation. Some of the vessels can be closed by means of cautery or diathermy applied to the vessel trunks at the limbus for 2 mm. He has done a very large number of these and, in general, his results were unsatisfactory. About 80 percent of the vessels soon reopen. Stripping is helpful when the vessels are large and superficial. He has done relatively few of these, but again, results of stripping alone are disappointing. Radiation is the most effective method when

combined with stripping or peritomy.

The radiation can be either X ray or radium. The effect is identical, if filters are used to get the same rays through. Radiation, however, works only on tiny vessels and new capillaries, so the larger trunks require the other methods.

The more popular method at present is to use Beta radiation by means of radon or radium in a special small pencil-like applicator as designed by Dr. Burnam at Johns Hopkins. With very slight care this can be applied by the ophthalmologist himself to the blood vessels for the requisite number of gram seconds.

Dr. Paton spoke of accidentally cutting sutures. It is disconcerting but not serious when one is occasionally cut. The cut suture may be pulled through and rearranged so that an extra knot can be tied. If this is impossible, a new suture can be inserted in the same holes or new ones, even though the eyeball is open, by using a little needle counter-pressure instrument. This instrument has two little pronged feet that stick against the cornea. The needle can be pushed between these feet without much trauma to the cornea. This instrument is also handy for repairing traumatic corneal or scleral wounds.

Among the postoperative complications, anterior synechia has been the most common in his experience. A slight anterior synechia at the edge of a clear graft is almost certain to cause clouding of the graft in a few months. It may cause proliferation of connective tissue on the back of the graft, or it may cause a haziness to the stroma and edema of the epithelium like dystrophy. There is also, of course, the danger of glaucoma.

If these synechias are freed through a small limbal incision without iridectomy, there are usually new anterior synechias created near the limbus. Dr. Leahey has freed anterior synechias on three of these cases (and also on some cataracts with

beginning edema of the cornea at the site of adherent iris pillars) by a simple and effective procedure. A scleral incision is made as for a cyclodialysis, but located only about 3 mm. outside of the limbus. The iris repositor is slid into the anterior chamber and the synechias swept away.

Proliferation of connective tissue on the back of the graft is not uncommon. It is practically sure to occur in the presence of anterior synechias. In other cases it grows in from fibroblastic tissue at the margin of a perfect graft. We have no treatment for this, as radiation here is not considered effective. Fortunately many cases may proliferate in only 1 mm. or so and then stop just about the time we are really getting worried.

Edema of the graft is another untreatable complication—provided it is not the result of anterior synechias or glaucoma. It may remain after operation; or some cases may be clear for 6 to 10 months, then suddenly develop slight edema of the graft and remain that way. Hypertonic saline or glycerine and vitamins seem to make no difference. One of the reasons for this edema is excessively dense scar tissue around the graft so that it has defective nutrition.

A minor complication which Dr. Leahy often finds is a large astigmatic error. He has a number of cases in which vision is near normal with cylinders of between 2 and 7 diopters. In one recent case having both a transplant and a cataract extraction, vision was improved to 20/30 and J1 with a: +4.00D. sph. \ominus 12D. cyl. Vision in these cases could be improved to 20/20 with contact lenses. Although he is doing a lot of contact-lens work, he has not yet prescribed one for a transplant case. Incidentally, in cases such as this, in which, both the cataract and the transplant are necessary, the transplant should always be done first and the cataract extraction second.

In closing, Dr. Leahy said that although the unpleasant features of this operation have been presented, he is very enthusiastic about the results of this procedure and that, in case of need, he would not hesitate to recommend the operation to a member of his own family or to submit to it himself. He added that in this event he would be glad if Dr. Paton were the surgeon working on him.

DR. EDWIN DUNPHY then spoke of the organization of the Eye-Bank in Boston as a branch of the Eye-Bank in New York. On Dr. Dunphy's request, Dr. Paton discussed the organization and operation of the New York Eye-Bank, stressing the need of the material not only for keratoplasty, but also for research.

Mahlon T. Easton,
Reporter.

SOCIEDAD OFTALMOLOGICA DE MADRID

January 17, 1947

SUPRASellar CHORISTOMA

DR. OBRADOR, DR. BARTOLOZZI and DR. CARRERAS MATAS presented a patient in whom the ophthalmic examination disclosed bilateral papillary atrophy, with total loss of vision in the left eye and a scotoma in the upper temporal quadrant of the right eye. The diagnosis was a probable suprasellar tumor. Dr. Obrador operated and removed a tumor which was situated between the optic nerves in front of the chiasm. The anatomic-pathologic examination showed that it was a choristoma. A few days after the operation the visual field of the right eye was considerably improved, and the acuity of this eye rose from 3/50 to 9/10.

Discussion. Dr. Marin Amat: This morning I saw the patient in my ophthalmologic service in the Provincial Hospital and could see total atrophy of the papilla of the left eye and partial atrophy of the

papilla of the right eye; but since in the latter eye the atrophy had all the characteristics of a postneuritic atrophy (thickened contour of the papilla, thin arteries), I wonder if in the beginning, before being operated, it might have been treated as a case of Foster-Kennedy Syndrome. The result is clear, the finding and the extirpation of the tumor.

Professor Carreras. The case which has just been discussed by Dr. Bartolozzi and Dr. Carreras Matas, as ophthalmologists, and by Dr. Obrador, as a neurosurgeon, shows how necessary it is to have the collaboration of the ophthalmologist, the internist, and the neurosurgeon in order to treat with the greatest degree of skill a clinical case which is more or less complicated and which none of the specialists working alone could have solved satisfactorily. The fact that this patient shows complete amaurosis of one eye with complete optic atrophy; and, in the other eye, incomplete optic atrophy, with a visual-field defect of a complete upper temporal and part of a lower temporal sector, the vertex of the sector reaching onto the fixation point, makes me diagnose the case as one of an intracranial lesion (probably a tumor) which started in the chiasmal region and which extended mainly toward the left side interfering with most of the crossed fibers from the right side and all the fibers (crossed and uncrossed) of the left optic nerve. My diagnosis is supported by the fact that the X-ray studies show the sella turcica to be apparently normal.

CONJUNCTIVAL COVER FOR INJURY

DR. MARIO ESTABAN showed a case of a penetrating injury to the eye. There was a scleral tear of about 7 mm. at the edge of which vitreous began to appear. His first thought was to enucleate the eye; however, he limited himself to the use of a conjunctival cover. The eye recovered and has vision of 2/3.

In ocular traumas we shall be better surgeons if we do fewer enucleations. It is necessary to adopt a conservative attitude when there is something which can be saved.

Repair of a scleral wound can be made either by closing the edges or by using a covering of conjunctiva. A good method of treating the edges directly is to use a double-armed suture which brings the edges of the sclera and conjunctiva together at the same time. There is, however, the disadvantage that one has to exert pressure on the globe in order to force the needle through the fibrous tissue of the sclera.

A conjunctival covering, on the other hand, can be made easily and without pressure. One good method is to detach the conjunctiva at one of its edges and bring a small strip over to the opposite side so that when the suture is made the conjunctiva slides over the scleral wound and keeps it covered.

Discussion. Dr. Carreras said that he agreed with Dr. Mario Estaban that one should not be hasty to enucleate an eye which is seriously injured, although the chances of saving it may be small. Some 21 years ago he published a paper, describing the case of a patient who, during a wild carnival frolic, had a lemon thrown in his face with such force that it broke the lens in front of his left eye and caused the temples of the frame to cut the eye, causing a wound which took in the whole vertical meridian of the cornea and included some 5 mm. of the sclera. There was a hernia of the iris and of the ciliary body, and vitreous appeared at the edges of the wound. The patient was rushed to a first-aid station, where the doctor did nothing but put a sterile pad on the eyes and advise that he be taken to an ophthalmologist for removal of the eye. Operating on him the same night, I reduced the hernia of the iris, sutured the cornea and the sclerotic, and then made a conjuncti-

val covering. After a binocular bandage had been applied, the patient was put to bed and protein therapy was started. The result was that the eye was cured. Final vision was $2/3$, and a myopia of 3 diopters, which the patient had had before the accident disappeared. The lineal cicatrix of the cornea is hardly visible.

Dr. Mario Estaban answered Dr. Carreras, thanking him for his discussion which supported his conservative procedure.

OPHTHALMOLOGIST AND CRANIAL SURGERY

DR. MARIO ESTABAN read a paper on "The Collaboration of the Ophthalmologist in Cranial Surgery in War."

War wounds produce a large number of serious cranial lesions in which it is rare not to find the ocular system more or less affected. The collaboration of the ophthalmologist and the surgeon is always effective and often indispensable for diagnosis, in treatment, and during the progress and postoperative course of cranial injuries. In diagnosis, the ophthalmologist can outline the difficult types of vascular lesions, oculomotor lesions, and lesions of the optic pathways and give their topography. This will enable the surgeon to fix accurately the indications and localization of the operative procedure.

In treatment, the surgeon and the ophthalmologist can work together in a great many cases in which there are many wounds and mixed lesions of the cranium and the eyes.

During the progress and the postoperative course of cranial injuries, a systematic ophthalmoscopic examination will give the surgeon information of a favorable condition or will put him on guard against complications. Hemorrhagic symptoms may disappear or appear later. An oculomotor paralysis may disappear (a transitory compression of the

nerve fibers by blood or exudate which have been absorbed) or it may persist (a bony compression, which remains, or section of the fibers, which have not regenerated); new forms of paralysis may appear, the cause of which, mechanical or infectious, will have to be sought.

Repeated examination of the visual field gives valuable data on the location of the lesions, the importance and the progress of the lesions, as well as the sequelae of the surgical intervention. I am reminded of a case of a Moor who was very much surprised not to be able to read Arabic, a language which he knew very well, and to be able to read Spanish which he knew but slightly. What happened was that his wound destroyed totally the right occipital lobe, with a consequent left homonymous hemianopia. It also caused a partial destruction of his left occipital lobe, with the consequence of a partial right hemianopia. Reading Arabic from right to left was impossible because the visual field was lost on that side; whereas, reading Spanish from left to right (in the direction in which he still had a useful visual sector of the field) was possible.

With reference to the phenomena of cranial compression, repeated ophthalmoscopic examination and measurement of the retinal arterial tension gives pertinent information. Diminishing tension indicates that a subdural hemorrhage is reabsorbed; unchanged tension shows a collapse of the lamina interna; increased tension, a serous arachnoiditis. It is no less interesting to determine the presence of cranial hypotension, following a large loss of intracranial fluid. Many poorly explained cerebral disorders (headache, migraine, and so forth) may be due to this cause and may be diagnosed by the fall in pressure of the retinal arteries.

Directors: LAWRENCE T. POST, President; WILLIAM L. BENEDICT, Vice-President; DONALD J. LYLE, Secretary and Treasurer; WILLIAM H. CRISP, F. C. CORDES, DERRICK VAIL.

Address original papers, other scientific communications including correspondence, also books for review to *Dr. Derrick Vail, 700 North Michigan Avenue, Chicago 11, Illinois*; *Society Proceedings* to *Mrs. Katherine F. Chalkley, Lake Geneva, Wisconsin*. Manuscripts should be *original copies*, typed in *double space*, with wide margins.

Exchange copies of medical journals should be sent to *Dr. F. Herbert Haessler, 324 East Wisconsin Avenue, Milwaukee 2, Wisconsin*.

Subscriptions, application for single copies, notices of changes of address, and communications with reference to advertising should be addressed to the *Manager of Subscriptions and Advertising, 700 North Michigan Avenue, Chicago 11, Illinois*. Copy of advertisements must be sent to the manager by the fifteenth of the month preceding its appearance.

Author's proofs should be corrected and returned within forty-eight hours to the *Manuscript Editor, Mrs. Katherine F. Chalkley, Lake Geneva, Wisconsin*. Twenty-five reprints of each article will be supplied to the author without charge. Additional reprints may be obtained from the printer, the George Banta Publishing Company, 450-458 Ahnaip Street, Menasha, Wisconsin, if ordered at the time proofs are returned. But reprints to contain colored plates must be ordered when the article is accepted.

THE 1947 ACADEMY MEETING

The 52nd annual session of the American Academy of Ophthalmology and Otolaryngology was held at the Palmer House in Chicago, October 12 to 17, 1947. A few more than 3,400 members and guests, some of whom were from the distant corners of the world, registered for the meeting. The weather was kind, although perhaps a little too warm, and the aura of the meeting was cheerful. For a short time at least, the members could forget the distress of the world and the

various political and economic conflicts that have been rubbing us into a state of irritability. The excellence of the program, the splendid and numerous instruction courses, the enjoyable social evenings, and a scientific exhibit that was better than average contributed to the evident success of the meeting. Under the able and wise guidance of the president, Alan C. Woods, of Baltimore, and the other officers of the Academy, the scientific sessions were conducted with expedition and dignity, worthy of the important

subjects that were discussed. Dr. Fredrick H. Verhoeff of Boston was the guest of honor. His prestige as investigator, surgeon, clinician, and teacher, and geniality and wit assured the members that the choice was a happy one. The affection and respect that the members hold for Dr. Verhoeff was attested to on many occasions during the meeting by prolonged applause and the award of a plaque by the Academy as a testimony to his outstanding service to ophthalmology.

In his president's address, Dr. Woods spoke on the present policies of the specialty board and the national societies in relation to the progress of ophthalmology. He pointed out the great influence of the various boards in the elevation of the standards of training and practice of the specialties during the past 30 years. He deprecated, however, the tyrannical requirement of a certificate by various hospitals, universities, and government services, in order to permit hospital practice, teaching advancement, or extra financial allowances. He suggested that it is now time to reconsider these requirements and to liberalize them. Dr. Verhoeff discussed, in inimitable fashion, the subject of "Some Problems Concerning Convergence." His address showed evidence of deep and prolonged thought on the subject and will deserve careful reading. The symposium on "Psychosomatic Manifestations" turned out to be an agreeable surprise, and those who were repelled by the formidable title, but stayed to listen anyway, were rewarded by the stimulating talks of Dr. T. A. C. Rennie on the "General Aspects," Dr. C. Stewart Nash on "Otolaryngology," and Dr. D. O. Harrington on "Ophthalmology." The members who were not present missed something noteworthy.

The symposium on "Corneal Transplantation" was arranged, logically discussed, and summarized so ably by the

collaborators, that it comprises an important and most significant scientific contribution to this widely publicized and spectacular subject. The finding that only 36 percent of 416 cases had a clear transplant will be most sobering to us after all that we have read in the newsprint about keratoplasty. The symposium showed that coöperative clinical studies such as this are of great value and the method should be applied to other subjects as well.

Dr. Otto Barkan's paper on "Technique of Goniotomy for Congenital Glaucoma" was outstanding. His contribution, the value of which is now rapidly being recognized everywhere, has stood the test of time and experience. Goniotomy is here to stay, beyond question, and is the only operation for this distressing and blinding condition that offers much hope for the affected infants. Other papers of ophthalmic interest are likewise worthy of remark, for the quality of the program was unusually good. The moving pictures, however, were disappointing, on the whole, in subject matter and presentation, although the photographic technique was excellent in most cases.

One hundred and nine individual and 30 continuous instruction courses in ophthalmology were given by 163 instructors. A total of 368 hours of instruction was provided, and each course was filled practically to overflowing. The demand for and the attendance of the courses show how valuable the members think they are. Thus, they maintain first place in the affection of the members and guests, who are hungry for such instruction and beg for more each year.

Dr. Francis Heed Adler gave the fourth Jackson Memorial Lecture on the subject of "Paralysis of Vertical Muscles," and Dr. Robert Thompson Tidrick delivered the second Wherry Memorial Lecture on "Advances in Surgical Hemostasis: Evaluation of Absorbable Agents."

Both of the lectures were most ably executed, and the audience was highly rewarded. This feature of the Academy meeting is assuming a conspicuous position in the affairs of the institution.

Two hundred and 64 candidates were admitted to membership this year, of whom 120 were ophthalmologists. Dr. Conrad Berens was chosen as president elect to serve in 1949, Dr. Ralph Ry-chener was elected first vice president, and Dr. Ray K. Daily was elected third vice president from the ophthalmologists. Cols. Dart and J. E. Ash of the U. S. Army Medical Department, Dr. Charles Sheard of the Mayo Clinic, and Mrs. Helenor Campbell Wilder of the Army Medical Museum, were elected honorary members. The Leslie Dana Medal of the St. Louis Society for the Prevention of Blindness was awarded to Dr. Verhoeff for his great services in the prevention of blindness.

The exhibits of Dr. K. W. Ascher (Aqueous Veins), Dr. Posner and Dr. Schlossman (Glaucoma), and Dr. A. D. Ruedemann (Radium in Ophthalmology) won first prizes in their respective classes. The exhibit by Dr. R. G. Ingalls on "Intraorbital Tumors" received honorable mention. Dr. Benjamin Rones' exhibit on "Ophthalmology in Cartoon" provided a delightfully light and humorous touch. It was cleverly arranged at the entrance to the exhibits and put one in a good humor both on entering and leaving.

The commercial exhibits were numerous and well displayed. Newer pieces of equipment, apparatus, instruments, and devices were to be seen and handled without trouble and in comfort. Their respective merits were the subject of vehement discussions by groups here and there.

The continuous success of these meeting testifies to the efficiency and hard work of the executive secretary, Dr. William L. Benedict, and the staff of secretaries

and officers of the Academy. There is no question of the sincere gratitude and appreciation of every member for their great services.

DERRICK VAIL.

THE FINAL OPHTHALMOLOGICAL STUDY COUNCIL COURSE

This summer the third and last Basic Course in Ophthalmology of the Ophthalmological Study Council has been in full cry, housed at Westbrook Junior College, in Portland, Maine. "Cry" is perhaps an inappropriate word, as the students who brought their families, with 30 children in all, had only four of the crying age or young enough to be properly termed "wetting agents." Families with infants occupied a small dormitory by themselves which had a kitchen, icebox, and laundry. Milk and diaper service were in attendance when they arrived. Single men, married couples, and families with children were housed in separate buildings.

The enrollment was the largest of the series, numbering well over 100. In addition, a small number of students came for part of the curriculum. Over half of the United States was represented. The first registrant was the long-distance champion. He had been serving as a medical missionary to Nigeria, in Africa. He drove from California, with wife and children, in a trailer complete with grandmother. In view of the already strained accommodations at the College, the requirement that students reside on the campus was cheerfully waived and this consignment went off to a trailer camp. Another outsider came from Honolulu. There were also seven Canadians. Seventy were veterans of World War II.

From a physical standpoint, it looks as though the course had finally hit upon the

ideal arrangement. Because the college was designed as an educational institution, the facilities were well adapted to the purpose, instead of the rather makeshift accommodations of the previous courses. The housing and food were more generous than the other ventures, yet the college gave the lowest rates so far. Besides the bedrooms, families had a sitting room, and the recreation rooms of the dormitories were also available. The College authorities and the chamber of commerce interested themselves in the entertainment of the visitors. This was not difficult, as Portland is a considerable tourist center, with lakes, mountains, and beaches nearby.

The course opened on the first day without rain for some weeks. Credit for this achievement was claimed by the city manager in a speech of welcome at an outdoor picnic on the opening day, given by the College to all members of the course. Steak was served—more steak, in fact, than was known to exist in this area. Other picnics were arranged, including a New England clambake for one weekend. This is a form of dissipation indigenous to this region, characterized mainly by unlimited quantities of lobsters, clams, potatoes, and corn, cooked in a cairn of hot stones and seaweed on the beach. Dismembering the shellfish is a trick second only to eating with chopsticks, and should be excellent preparation for the more difficult ophthalmic operations.

The faculty was a trifle larger, and, as in the previous courses, the instructors were distinguished teachers from many parts of the country. A few more subjects were added, such as lectures on therapeutics intended to prepare the students better for clinical work as residents and preceptees.

The instructors were surprised by the enthusiasm and industry of the classes.

This is, however, only the general experience of all educational institutions engaged in the training of veterans. The pleasant associations of this group, thrown together for an entire summer in this way, should naturally be renewed at future medical meetings, giving the members a ready-made group of friends. It ought to ease some of the curse of the meetings for the women at least. The council are convinced that one factor in keeping up the momentum was the weekly shot in the arm furnished by the interim examinations in the subjects covered.

The Study Council is being pressed to rescind the termination of these courses and hold another here next summer. No decision can be reached until the annual meeting of the Foundation of Vision of which this course is a subsidiary.

S. Judd Beach.

OBITUARY

THOMAS HALL SHASTID,
(1866-1947)

Dr. Thomas H. Shastid, ophthalmologist and author, died February 15, 1947, at his home at Duluth, Minnesota, at the age of 80 years. He was born at Pittsfield, Illinois, in 1866. He became his father's medical apprentice at the age of 10 years. From 1883 to 1886, he was a student at Eureka College, Eureka, Illinois. He studied medicine at Columbia University and the University of Vermont, receiving his Doctor of Medicine degree with honors at the latter institution in 1888. His B.A. degree was granted him later at Harvard where he graduated cum laude in 1893. He did postgraduate work at the New York Postgraduate Medical School, at the University of Vienna, and the University of Michigan. The degrees of Master of Arts and Bachelor of Laws were granted at Michigan. He received

the honorary degree of Doctor of Science at the University of Wisconsin in 1922.

Dr. Shastid practiced medicine at Pittsfield, Illinois, from 1889 to 1891; at Galesburg, Illinois, from 1894 to 1897; at Fairfield, Illinois, in 1903; Charleston, 1904; Marion, Illinois, 1905 to 1913. He held the chair of professor of History of Medicine at the American College at St. Louis from 1907 to 1912. In 1914, he specialized in ophthalmology and was certificated by the American Board in 1917. He moved to Duluth, in 1922, where he resided until his death.

He was a member of the American Medical Association, American Academy of Medicine, American Medical-Legal and Toxicological Society, American Academy of Ophthalmology and Otolaryngology, American College of Surgeons, American College of Physicians, American Association of the History of Medicine, International Congress of Ophthalmology, Author's League of America, and numerous other societies. Dr. Shastid was an author of note as well as an ophthalmologist, and his score and more of published works cover such subjects as medicine, international peace, and war profiteering. He wrote two autobiographies, as well as several novels. The best known of his novels was *Simon of Cyrene*. He translated numerous medical volumes and journals from German, French, Latin, and Greek, and was a frequent contributor to scientific journals of all kinds. He also contributed heavily to the American Encyclopedia of Ophthalmology.

Dr. Shastid was an enthusiastic bibliophile. His library at the time of his death contained some 15,000 volumes and covered a wide variety of subjects. Every volume was carefully and systematically indexed. Book lovers gathered from far and wide when it was learned that his library was to be sold. There were

books on slavery, witchcraft, medicine, law, literature, philosophy, theology, history, music, and numerous other subjects. There were a number of rare old volumes including *Fitz-Herbert's Justice*, published in 1541. The library also included a collection of letters and signatures of famous people. Among them were a number of original copies of Abraham Lincoln's law briefs written in his own handwriting, a personal letter from Jefferson Davis, and communications from Henry Ward Beecher and John Jacob Astor. Dr. Shastid's wife died in 1940. After her death, he devoted much of his time to his books. Surviving him are an adopted daughter, Mrs. Donald R. Husband of Eugene, Oregon; two brothers, John S. Shastid, Kansas City, Kansas, and Joseph Shastid, Pittsfield, Illinois; and a nephew, John B. Shastid, New Castle, Pennsylvania.

A. C. Hilding.

BOOK REVIEWS

SENSORY MECHANISMS OF THE RETINA. With an appendix on electroretinography. By Ragnar Granit, M.D. New York, Oxford University Press, 1947. 412 pages, 178 illustrations, bibliography, and index. Price, \$11.00.

For the past 20 years Professor Granit and his many co-workers in the Royal Caroline Institute at Stockholm have zealously investigated the electrophysiology of the retina. The remarkable achievements in this field are now systematically and lucidly expounded. Probably the ophthalmologists of tomorrow will be as familiar with the pattern and interpretation of the electroretinogram as the internists of today are with the electrocardiogram. A pioneer text on clinical electroretinography has already appeared (Karpe, 1945), and Granit confidently predicts that the time will come when the record-

ing of the electroretinogram will be one of the standard methods of every well-equipped ophthalmic clinic, particularly in cases where, owing to opacities of the media, there is difficulty in making an ophthalmoscopic examination or using subjective tests.

The only means of securing information about the fast processes occurring in the retina itself lie in the electrical changes. Discrimination of intensity and contour are functions of the frequency and pattern of the optic-nerve discharges, respectively. The phases of excitation and inhibition emphasize the intensity gradient and give the higher centers the clue for sharpening impressions. The electroretinogram provides an objective basis for the analysis of visual sensation, and in the inter-relations of intensity, area, and duration of the stimulus have amplified the conclusions obtained through subjective methods. Various studies, including that of the pure rod retina of the guinea pig, indicate that besides the rods which accurately reflect the course of visual purple regeneration there are others, "cone" rods, which remain active after light adaptation, the difference being, apparently, wholly at the photochemical level.

A product of Granit's research is his challenging "dominator-modulator theory" of color vision. The scotopic curve is the only one obtainable from the dark-adapted eye, but in the light-adapted state certain elements show with his microelectrode technique restricted sensitivity curves, which Granit terms modulators. So far seven types of modulators have been found—two in the red, three in the green, and two in the blue. Units related to the rods appear responsible for the reception of short-wave lengths. Hue discrimination is best at 5,800 to 6,000 A.U., and 4,800 to 5,100 A.U., where the modulator curves overlap. The dominator curve rep-

resents the interaction of closely linked modulators acting as a functional unit. Such convergence could be the result of lateral connections through the amacrine cells, or synchronized impulses. The dominator and modulator mechanisms produce the fundamental sensations of brightness and color, respectively, which are to some extent independent of each other, as shown in deuteranopic color-blindness.

The numerous graphs which at first glance give the book an abstruse and formidable appearance are actually simple, carefully selected, and serve well in bringing the laboratory to the reader.

James E. Lebensohn.

EYE SURGERY. By H. B. Stallard, M.B.E., M.D., F.R.C.S. Baltimore, Maryland, The Williams & Wilkins Co. 444 pages, 338 illustrations. Price, \$11.00.

This new book on surgery of the eye is well worth the careful scrutiny of the ophthalmic surgeon. Most of the standard procedures are clearly and concisely given. As one would expect, the drugs and routines are more English than American. The emphasis on war surgery is greater than might have been expected in a text for peace time, but this is natural in a postwar surgical presentation. Many illustrative cases are given and these, especially the plastic, are mostly of battle casualties.

The reviewer is not convinced that illustrative cases, unless used very concretely to point out some definite thought, are of great value. No two plastic repairs are exactly the same and perhaps a textbook does well to restrict the number of such cases. This book, however, does not go to great lengths in this matter and most of the material is well chosen.

Some interesting new material is in-

cluded, such as the very simple operation for pterygium used by Sabri Kamel in Egypt in a great number of cases with complete success even in recurrences; and the operation by the late Sir Richard Cruise for chronic simple glaucoma. Among drugs not often used in the United States that are recommended are "novri-tox," a solution of novocaine, quinatoxine, benzoic acid, Ringer's solution, and adrenalin. For wide dilatation 'mydri-caine," a compound of atropine, cocaine, and adrenalin, is suggested.

For intraocular operations the patient is advised to enter the hospital two days before operation. Liquid penicillin is instilled the night before operation.

American surgeons may be somewhat surprised that the method of corneal section with scissors for cataract extractions, now so popular in this country, is not mentioned except as an adjunct when too small a section is made with a cataract knife. In discussing corneoscleral sutures, the reader naturally expects a description of the Stallard suture but is surprised at the omission of the McLean. The important surgery of retinal detachment will be found to coincide very closely with that practiced in this country. The use of a long needle in cases of high detachment is advocated "so that its point reaches the retina, or nearly so, but does not pass through it." This sounds somewhat theoretical to the reviewer. The use of pinhole spectacles is advocated postoperatively,

but advice as to how long they are to be worn is missing.

A chapter is devoted to traumatic surgery, chiefly military. The posterior route for removal of intraocular foreign bodies in the vitreous is the method of choice according to Stallard, differing from the practice current in the First World War.

All in all this text seems sound and well presented. It is a good supplement to one's surgical library.

Lawrence T. Post.

ALTERATIONS DE LA RÉTINE EN RAPPORT AVEC LES AFFECTIONS GÉNÉRALES. By Paul Bonnet. Report presented to the Société Française d'Ophthalmologie, May 18, 1947.

The first volume of this most-praiseworthy atlas of ophthalmoscopy was reviewed in the March, 1947, issue of the JOURNAL. This second volume is no less interesting. It follows the same plan as its predecessor and is equally well printed. There are 253 pages of text with 41 illustrations. There are 83 beautiful, interesting, and instructive fundus drawings on 36 plates.

The lesions discussed are predominantly associated with disturbances of the hematopoietic system, namely, anemias, leukemias, angiomas, hemolytic icterus, Banti's disease, and a few less closely related syndromes.

F. H. Haessler

ABSTRACT DEPARTMENT

EDITED BY DR. F. HERBERT HAESSLER

Abstracts are classified under the divisions listed below, which broadly correspond to those formerly used in the Ophthalmic Year Book. It must be remembered that any given paper may belong to several divisions of ophthalmology, although here it is mentioned only in one. Not all of the headings will necessarily be found in any one issue of the Journal.

CLASSIFICATION

1. General methods of diagnosis
2. Therapeutics and operations
3. Physiologic optics, refraction, and color vision
4. Ocular movements
5. Conjunctiva
6. Cornea and sclera
7. Uveal tract, sympathetic disease, and aqueous humor
8. Glaucoma and ocular tension
9. Crystalline lens
10. Retina and vitreous
11. Optic nerve and toxic amblyopias
12. Visual tracts and centers
13. Eyeball and orbit
14. Eyelids and lacrimal apparatus
15. Tumors
16. Injuries
17. Systemic diseases and parasites
18. Hygiene, sociology, education, and history
19. Anatomy, embryology, and comparative ophthalmology

7

UVEAL TRACT, SYMPATHETIC DISEASE, AND AQUEOUS HUMOR

O'Donnell, J. M. Behcet's triple syndrome. *M. J. Australia*, 1947, June 14, pp. 730-732.

The author reports a case of Behcet's syndrome. The patient had small punched out ulcers of the scrotum and mouth, conjunctivitis, iritis, epididymitis, geographical tongue and gastric disturbances. High doses of ascorbic acid helped in the recovery.

Irwin E. Gaynon.

Rados, Andrew. Central pulverulent (discoid) cataract and its hereditary transmission. *Arch. of Ophth.*, 1947, v. 38, July, pp. 57-77.

The author gives a detailed description of this type of cataract (also known as Coppock or Doyne cataract) and analyzes the hereditary transmission. The family trees reported in this paper and the literature show that the mode of inheritance is dominant. (9 figures, 31 references.) R. W. Danielson.

Rio Cabanas, J. L. Bilateral metastatic pseudoglioma. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1947, v. 7, April, pp. 380-384.

An infant, 26 months of age, developed an acute febrile exanthema, with nephritis. The exact nature of the infection was not diagnosed, but it was probably a streptococcus septicemia. A few days after the onset of the disease both eyes developed symptoms of a violent uveitis with hypopyon, and soon afterwards a yellowish conglomerate mass resembling a glioma appeared in the vitreous of each eye. The diagnosis of a metastatic pseudoglioma was made, and the outcome was atrophy of one eye, and doubtful light perception in the other. It is believed that penicillin therapy prevented the development of a panophthalmitis. Ray K. Daily.

Solanés, M. P. The Vogt-Koyanagi syndrome. *Anales de la Soc. Mexicana de Oft.*, 1947, v. 5, Jan.-March, pp. 12-23.

The new cases of this disease now reported raise to nine the number

placed on record in Mexico. The ages of these two patients were respectively 25 and 28 years. The former was five and a half months pregnant.

The symptoms included various forms of uveitis; poliosis of the eyelashes, eyelids, and axillas; alopecia and vitiligo; hyperacusia, dysacusia, and deafness, in addition to general neuropathic and febrile manifestations.

Slow recovery of vision occurs, but the vision never returns to normal. Occasionally there is secondary glaucoma, or phthisis bulbi. (References.)

Stine, G. H. Detachment of the choroid and the retina. Anatomic and other considerations in the differential diagnosis. *Amer. Jour. Ophth.*, 1947, v. 30, July, pp. 897-907. (See Section 10, Retina and vitreous.)

Stocker, F. W. Experimental studies on the blood-aqueous barrier. *Arch. of Ophth.*, 1947, v. 37, May, pp. 583-590.

It has been demonstrated by numerous authors, especially by the splendid work of Duke-Elder and Friedenwald and their co-workers, that the penetration of the various constituents of aqueous through the blood-aqueous barrier follows a rather complicated scheme. Electric charge, size of the molecule and possibly other factors influence the ratio of transmission of each constituent. But, on the other hand, it has also been shown that any change of the permeability of the blood-aqueous barrier will affect all constituents to a certain extent, though not equally, whether they are electrolytes, nonelectrolytes or proteins.

There is little doubt that the permeability of the blood-aqueous barrier plays an important part in certain cases of glaucoma. It also is known and con-

firmed by the experiments in part II of this study that the drugs generally spoken of as miotics not only contract the pupil but also increase the permeability of the blood-aqueous barrier.

From this preliminary report, the following conclusions seem to emerge: (1) no appreciable influence on the permeability of the blood-aqueous barrier can be demonstrated when normal rabbits are fed large doses of rutin for three weeks, and (2) the action of physostigmine, which is known to increase the permeability of this barrier after being instilled into the conjunctival sac, is greatly reduced if the animal has been rutinized. Vanzetti, G., and Seidenari, R. The composition of the aqueous humor, particularly the glucose and chloride content. *Rassegna Ital. d'Ottal.*, 1947, v. 16, Jan.-Feb., pp. 65-77.

Chemical determinations by means of micromethods were made upon samples of 0.88 cc. of aqueous in a series of normal and pathologic eyes. Details of the procedure and results of individual determinations are given in the article. The average chloride content was found to be the same as that of the blood serum, 6.499 gm. per 1,000 cc. and of glucose 0.727 gm. The latter figure is sensibly lower than that given by Ash and less than the percentage in the blood. No appreciable change in the protein content was found. (2 tables, 19 references.)

E. M. Blake.

Vianna, Louzada. Tuberculin therapy in the uveitides. *Rev. Brasileira de Oft.*, 1947, v. 5, June, pp. 195-207.

The author believes the following facts should be kept in mind in dealing with the possibility of a tuberculous

etiology: Tuberculous infection is the rule and its existence in the adult may be assumed. This disease in the eye may frequently take on the appearance of an ordinary inflammation without specific character. Tuberculin has curative action in certain tuberculous processes.

The author has studied 142 cases of endogenous affection of the uveal tract, in the past 18 months. Many had had antisyphilitic treatment and others were still undergoing such treatment. Eighteen cases are summarized as having supported the belief that improvement obtained was clearly associated with tuberculin therapy. The tuberculin is kept in dilutions running from 1 to 10 up to 1 to 1,000,000, which are in practice referred to as 1—zero up to 6—zero. (References.) W. H. Crisp.

Vidal, F., and Brodsky, M. Physiopathologic considerations concerning a case of post-traumatic anisocoria. *Arch. de Oft. de Buenos Aires*, 1946, v. 21, Aug., p. 235.

After a gunshot wound of the neck, a patient presented an arteriovenous aneurysm of the left carotid artery, with exophthalmos, conjunctival hyperemia, marked vascular engorgement of the fundus and slight peripheral contraction of the nasal field of the same side. There was also ptosis of the upper lid and miosis due to a lesion of the cervical sympathetic fibers. Resection of the aneurysm brought about gradual improvement of the exophthalmos and vascular disturbances, but the ptosis and miosis remained unchanged. Pharmacologic tests confirmed the sympathetic nature of the latter condition. (Bibliography.)

Plinio Montalván.

Yasuna, E. R. Danger of penicillin

therapy in active uveitis. *Arch. of Ophth.*, 1947, v. 37, May, pp. 598-607.

A review of the literature of the use of penicillin in various eye diseases is followed by two case reports of uveitis in which the penicillin seemed to hinder rather than favor the healing process. The author explains this apparent action by mentioning the recent theories that uveitis is caused by bacterial toxins and products of bacterial degeneration rather than by the bacteria.

Thus destruction of the bacteria in the focus of infection could aggravate the uveitis.

He concludes that penicillin in the treatment of uveitis does not appear to offer any advantages over previous methods and may cause the uveitis to persist longer than it would otherwise. (41 references.) R. W. Danielson.

GLAUCOMA AND OCULAR TENSION

Baillart. Infantile glaucoma in a national institution for the young blind. *Ann. d'Ocul.*, 1947, v. 180, May, pp. 257-262.

This analysis of 40 patients with infantile glaucoma shows that the tension was surgically brought to normal in only half of those operated upon. Blindness is not only caused by increased ocular tension but also by subsequent atrophy. Twenty-three percent of the patients admitted between the ages of 8 and 18 years had infantile glaucoma. Boys were affected more frequently than girls in the ratio of five to three.

Only five percent of the total infantile glaucomas were due to congenital syphilis and an equal number occurred in children whose mothers had rubeola in the first months of pregnancy. In 17 percent of the cases the infantile

glaucoma was familial. Latent or actual hydrocephalus was associated in approximately 25 percent and buphthalmos existed with infantile glaucoma in 67 percent. Nine eyes had been enucleated before admission and 60 percent of the patients who had had surgical treatment were totally blind.

Chas. A. Bahn.

Bárány, Ernst. The influence of local arterial blood pressure on aqueous humor and intraocular pressure. An experimental study of the mechanism maintaining intraocular pressure. *Acta Ophth.*, 1947, v. 25, pt. 1, pp. 81-94.

This second investigation in this field deals with the recovery of intraocular pressure, arterial blood pressure, and heat dissipation by the external ear after unilateral carotid ligation. The former investigation demonstrated that immediately after ligation the intraocular pressure maintains a constant level about 3.5 mm. below normal. The tabulated data of the results of the present study show that the intraocular pressure does not undergo any significant changes within the first 24 hours after ligation. During the following days a slight additional fall in blood pressure and intraocular pressure is followed by a return to normal. The intraocular pressure becomes normal more rapidly than the blood pressure. In some cases the intraocular pressure returns to normal, and the blood pressure remains considerably reduced. The difference in the progress of recovery of intraocular pressure and blood pressure is interpreted as an indication that the intraocular pressure has a defense mechanism against a fall in blood pressure, which enables the intraocular pressure to become normal in spite of a persistent and marked fall in blood pressure. The heat dissipation from the

external ears and the ear pressure behave like intraocular pressure. They recover much more rapidly than the blood pressure, and become normal simultaneously with the intraocular pressure. The similarity in the behavior of two completely different circulatory functions supports the view that the recovery of intraocular tension is due not to a slow acting regulation of the intraocular pressure, but to a general adaptation of the vascular bed to a low blood pressure. (7 graphs.)

Louis Daily, Jr.

Barkan, Otto. Cyclodialysis, multiple or single, with air injection—an operative technique for chronic glaucoma. *California Med.*, 1947, v. 67, Aug., pp. 78-83.

Cyclodialysis is indicated in primary glaucoma of the wide angle type, and is the operation of choice in cases of narrow angle glaucoma with peripheral adhesions. It is also indicated in certain types of secondary glaucoma, and in eyes in which other types of glaucoma operations have failed. In primary glaucoma the tension was normalized in 63 of 70 eyes. Of these 13 had the narrow angle type with peripheral adhesions, and all were normalized.

With the use of air injection immediately after the cyclodialysis, hemorrhage is controlled, the cleft is visible, and by restoring and deepening the anterior chamber, multiple cyclodialyses are made possible. Maximal miosis is maintained preoperatively and postoperatively, and a miotic is prescribed permanently to assure maintenance of the cleft and channel.

O. H. Ellis.

Barkan, Otto. Cyclodialysis, multiple or single, with air injection. *Amer. Jour. Ophth.*, 1947, v. 30, Sept., pp. 1063-1073. (4 figures, 11 references.)

Barry Rodríguez, Julio. Complex forms of glaucoma. Arch. de la Soc. Oft. Hisp.-Amer., 1946, v. 6, June, pp. 576-585.

The importance of the investigation of glaucoma is stressed in all cases of optic nerve atrophy especially in those of unknown cause. The author reports the case of a 67-year-old man who for several years was thought to have a simple bilateral optic atrophy. The diagnosis of glaucoma was made by means of the measurement of ocular tension and visual fields.

J. Wesley McKinney.

Biozzi, Giuseppe. Cyclodiathermy-puncture. Riv. di Oftalm., 1946, v. 1, Nov.-Dec., pp. 679-697.

Biozzi performed Vogt's operation on 31 patients. He used the original technique but extended the operative area over one half of the circumference, and applied 150 to 200 single punctures each time. The safety margin between doses that efficiently reduce pressure and dangerous hemorrhage is small. A current of 60 milliamperes was used. The author used cyclodiathermy puncture in 16 cases of chronic simple glaucoma, 12 of absolute glaucoma, 6 of glaucoma in aphacic eyes, 2 of secondary glaucoma, and one each of malignant, chronic irritative, and prodromal glaucoma. In the eyes with chronic simple glaucoma, the cyclodiathermy reduced the intraocular pressure ten times for a period of three to eight months, in three other eyes the period of postoperative observation was too short for conclusive classification, and in three a reduction of pressure lasted for about one month, when a second operation was followed by a pressure drop that lasted 2 and 10 months respectively. In three of the eyes with absolute glaucoma, the operation was

a failure, but the other eyes became painless and softer for at least some months. In two of the aphacic eyes, the pressure was controlled for 7 to 19 months; in one eye a second operation became necessary. The cyclodiathermy puncture may save some glaucomatous eyes that would otherwise be lost, and is indicated particularly after failure of other antiglaucoma operations. K. W. Ascher.

Bloomfield, Sylvan. Relative deficiency of parasympathomimetic activity in aqueous of eyes with chronic simple glaucoma. Arch. of Ophth., 1947, v. 37, May, pp. 608-617.

The purpose of this investigation was to determine experimentally whether a parasympathomimetic substance actually occurred in the nonglaucomatous human eye and to determine its identity if present. A series of eyes with chronic simple glaucoma was also studied to explore the possibility that some deficiency in the normal activity of such a cholinergic substance occurred in that disease. Since the aqueous humor is, in a sense, a perfusion fluid of the eye, and, with proper precautions, is safely obtainable by paracentesis from the living organ, the study of that fluid seemed suited to this purpose. Because of the pharmacologic nature of this investigation and the extreme dilution of the substances which are studied, biologic methods of assay were employed.

In 17 of 20 nonglaucomatous eyes with various noninflammatory pathologic conditions, an appreciable parasympathomimetic effect was demonstrable in the aqueous humor.

In each of seven eyes in which the aqueous humor could be further studied, this cholinergic activity was found to be due to the presence of acetylcholine.

In 15 of 20 eyes in various stages of chronic simple glaucoma, no such parasympathomimetic activity could be demonstrated in the aqueous humor. In the remaining five eyes in this series, the intensity of the parasympathomimetic activity present was significantly lower than that which occurred in the aqueous of the 17 nonglaucomatous eyes which produced cholinergic effects.

This relative deficiency of parasympathomimetic activity of the aqueous humor in eyes with chronic simple glaucoma was not altered by the successful treatment of the disease with various filtering operations.

There is evidence that this relative deficiency in parasympathomimetic activity of the aqueous of eyes with chronic simple glaucoma is related to the faulty regulation of intraocular pressure which occurs in that disease. (8 references, 4 figures.)

Bloomfield, Sylvan, and Kellerman, Leo. **The relative value of several diagnostic tests for chronic simple glaucoma.** *Amer. Jour. Ophth.*, 1947, v. 30, July, pp. 869-877. (8 figures, 17 references.)

De Torres Lucena, M. **Influence of atropine given intravenously on the ocular tension of primary glaucoma.** *Arch. de la Soc. Oft. Hisp.-Amer.*, 1946, v. 6, May, pp. 446-454.

This study was made on 62 patients with primary glaucoma, between the ages of 60 and 70 years. Intravenous injection of atropine sulphate in doses of 0.25, 0.50, and 0.75 mg. were given every six or seven minutes until the total amount reached was the amount given in the Vasquez-Danielopolu test. The ocular tension and pupillary measure-

ment were taken every 20 minutes in the first two hours and every hour thereafter until six were made. Hypotension was found in 34.1 percent, hypertension in 51.2 percent, and no deviation in 14.6 percent. All but three responded with mydriasis before the first two hours. In order to prevent a later hypertension, drops of 7-percent pilocarpine were given after the fifth hour.

J. Wesley McKinney.

Diaz Domínguez, Diego. **Spontaneous healing of glaucoma.** *Arch. de la Soc. Oft. Hisp.-Amer.*, 1946, v. 6, May, pp. 455-467.

The author reports in detail three cases of chronic glaucoma which had healed spontaneously.

J. Wesley McKinney.

Dunphy, E. B. **Di-isopropyl fluorophosphate in glaucoma.** *Bull. New England Med. Center*, 1947, v. 9, June, pp. 102-106.

DFP is a powerful, toxic miotic. The miosis persists up to 14 days and is present under full dark adaptation. It acts by destroying cholinesterase and reduces the tension in glaucomatous and normal eyes. In one-half of the eyes with glaucoma which did not respond to pilocarpine or eserine, DFP succeeded in bringing the tension to normal. Its ontoward effects are pericorneal injection, congestive iritis, and, occasionally, an increased ocular tension.

Irwin E. Gaynon.

Gallenga, R. **The operability of advanced chronic glaucoma.** *Rassegna Ital. d'Ottal.*, July 1943-Dec. 1945, v. 12-14, pp. 516-528.

Gallenga urges surgery in all cases of chronic glaucoma, regardless of the duration of the disease or the state of the fields of vision. He favors the fis-

utilizing type of operation. When the tension is very high a cyclodialysis is added to the trephine operation. He agrees with Lauber that there is a relationship between ocular tension and general arterial pressure, and takes measures to raise the latter when it is below normal. When one cannot lower the tension and raise the blood pressure, operation results in decrease of vision and fields. The author gives a formula for prognosticating the results of surgery based on the ocular tension, the retinal arterial pressure and the general blood pressure.

Eugene M. Blake.

Granville, Roberto. **Goniodialysis.** *Rev. Brasileira de Oft.*, 1947, v. 5, June, pp. 231-235.

The author's operation for chronic glaucoma secondary to anterior synechia consists of making a scleral incision with the lance keratome or the Graefe knife, 2 mm. from the limbus and 4 mm. long; and then passing a spatula through this incision into the anterior chamber and sweeping the spatula along the angle of the chamber, first for a quarter of the limbal circumference to one side and then similarly to the other side of the primary incision. The spatula, maintained in intimate contact with the posterior face of the sclera, should not penetrate beneath the sclera more than 2 mm. from the limbus. Two successful and two unsuccessful cases are reported. (2 illustrations.)

Just Tiscornia, Benito. **Exploration of the functional status of the arterioles, capillaries, and veins of the anterior ocular segment.** *Arch. de la Soc. Oft. Hisp.-Amer.*, 1947, v. 7, April, pp. 367-374.

This is essentially a review of the

work of Vidal and Malbran on vasoscopy. Reference is made to Vidal and Malbran's conception of the role of the various components of the vascular system in the maintenance of ocular tension. The ocular tension of 100 mm. Hg found immediately after death is considered the static ocular tension produced by the fluid content of the interstitial tissues. The pressure above that is designated as dynamic, and attributed to active circulatory processes, in which the capillaries perform the most important function. In angiosclerosis involving the arterioles the ocular tension is low, but if the disturbance involves principally the veins the ocular tension rises.

The tests for the functional integrity of the ocular arterioles, capillaries, and veins are described in detail. For the study of the ocular arterioles, which are stimulated by the fibers of the sympathetic, 5-percent ephedrine sulphate solution is instilled into the conjunctival sac five times, at intervals of one minute. The ocular tension and size of the pupil are noted before the instillation, and 20 to 60 minutes afterwards. In normal persons and in advanced angiosclerosis there is no effect. In a disturbance of the venous circulation there is a rise in the ocular tension. In neuro-circulatory asthenia, with a diminished blood supply, there is a lowered ocular tension. The ocular circulation may be improved by conjunctival instillation of 2-percent ephedrine sulphate combined with calcium chloride. The capillary activity is under control of the parasympathetic system in which acetylcholine is the chemical intermediary. One can substitute carbaminoilcholine for acetylcholine by the instillation of a one third-percent solution preceded by a wetting agent; this instillation affects ocular tension through

capillary action. In patients with a normal circulatory apparatus there is a rise in tension for three to five minutes which is produced by increased arterial capillary activity. Following the short rise is a slow fall in tension lasting 50 minutes; this fall is ascribed to the increased activity of the veins, which carry away intraocular fluid more rapidly than it enters. About 80 minutes from the beginning of the test tension begins to return to normal, which it reaches at the end of three hours. In inadequate venous activity the secondary fall in tension does not take place.

Another test determines the cholesterinase content of the anterior ocular segment. A drop of 1.8-percent solution of dimethylcarbamic ester of bromide of oxipheniltrimethylammonia is instilled in conjunction with a wetting agent. Within eight minutes the tension rises 3 mm. because of increased arterial capillary activity. After two to three minutes the tension returns to normal, as a result of increased activity of the venous capillaries. Normally the effect of the drug is insignificant. In incipient glaucoma the effect manifests itself chiefly on the pupillary sphincter and ciliary muscle. In advanced glaucoma the secondary fall in tension does not occur. Vidal and Malbran believe that the first change in primary glaucoma is an increased cholesterinase content in tissues which contain it normally, such as the retina, the iris, and the ciliary body; later as its quantity increases, it is found in the aqueous and the vitreous which do not contain it normally. The increased cholesterinase content leads to the circulatory disturbances and ocular edema that characterize the glaucomatous syndrome. The tests of vascular function demonstrate metabolic changes in the anterior ocular segment.

Ray K. Daily.

Kalt, Marcel. Iridencleisis in the treatment of secondary glaucoma. *Arch. d'Opht.*, 1947, v. 7, no. 1, pp. 18-27.

Kalt reviews the surgical procedures which have been used in glaucoma secondary to iridocyclitis and concludes that repeated paracentesis, iridectomy, cyclodialysis, and the corneoscleral trephine are inefficacious. He advocates iridencleisis, performed according to the method of Weekers, as the surgical procedure of choice. In 22 cases of iridocyclitis with secondary glaucoma he was able to control tension in 86 percent. In 60 percent of the cases there was an improvement in vision and in 50 percent of the cases the preoperative visual fields were maintained.

Phillips Thygeson.

Magitot, A. Thalamus and glaucoma. *Ann. d'Ocul.*, 1947, v. 180, Jan., pp. 1-9.

After 60 years of research, glaucoma continues to be ophthalmology's enemy number one. Due to the emphasis of corneoscleral filterability by the Heidelberg School, the vascular factor in glaucoma has been neglected. This factor largely determines the response of the individual eye to intraocular tension. As it is the intraocular venous pressure and not the arterial that is about proportionate to the intraocular tension, the vascular process is apparently primarily venous. The genetic degeneration of the intraocular vascular system is only part of a similar condition elsewhere in the body, as has been demonstrated by subungual capillaroscopic tests. Especially the metabolism of water and acetylcholine is involved. The frequent association of glaucoma with endocrine disturbances, especially those of the pituitary gland, is thus explained. Eyes structurally predisposed to glaucoma are hypersen-

sitive to sympathetic and parasympathetic stimuli in which the ductless glands play an important part. Bodily vascular hypersensitivity is closely associated with that of some of the diencephalic centers especially those in the thalamus. Here sensory perceptual and other stimuli are integrated into autonomic vascular responses with their attendant production of sympathin, acetylcholine and related substances. This thalamic hypersensitivity which is partly vascular helps us to better understand why pain and emotion, febrile intoxications such as epidemic dropsy, and the use of caffeine may precipitate or aggravate glaucoma.

The treatment of glaucoma is based chiefly upon the use of drugs which alter autonomic vascular function. Decompressing operations alone do not eliminate this vascular factor and therefore do not cure glaucoma. The psychoneurologic treatment as an adjunct to other means is becoming increasingly important. It is important in this treatment to make the patient realize that if he remains calm he increases the chance to avoid his potential blindness.

Malbrán, J. L., and Caretti, J. A. Glaucoma: early diagnosis. The vacuum cup test. Arch. de Oft. de Buenos Aires, 1946, v. 21, Oct.-Nov., p. 315.

The authors studied the value of the vacuum cup test of Werner Herzau as applied by Abreu Fialho to the early diagnosis of glaucoma. The vacuum cup is made of plastic material and is connected to a rubber bulb for the production of a vacuum. It is placed over the cornea of the eye under study and the vacuum is maintained for a period of five minutes, after which the behavior of the intraocular tension is studied with the tonometer. In normal

eyes there is a drop in tension immediately after the test to half or less of the original. The period of recovery lasts from 5 to 15 minutes during which the tension returns to the initial level, but never above it. In eyes with a very delicate conjunctiva, bulbar hemorrhages and edema may occur after the test and disappear in three to five days. After studying this test in normal and preglaucomatous eyes the authors conclude that any eye whose tension does not behave in the characteristic manner, must be considered as suspicious of preglaucoma. Eyes must be also considered as suspicious of preglaucoma when the tension falls, but recovers in five minutes or less, or if after the recovery, the tension climbs 10 mm. or more higher than the original figure.

The vacuum cup test is a valuable adjunct in the diagnosis of preglaucoma, but is not conclusive as a sole procedure. Its mechanism is unknown and Abreu Fialho advanced the theory that the neurovegetative nervous system is an important factor in it. No untoward effects have been observed after the test. (1 illustration, charts, bibliography.) Plinio Montalván.

Marlow, S. B. Field of vision in chronic glaucoma. Arch. of Ophth., 1947, v. 38, July, pp. 43-56.

In 1931, observations on 11 cases of chronic glaucoma showing the effect of reduced illumination on the field of vision were reported by the author. The present review has to do with 50 additional cases studied by the same method. Marlow concludes that the necessity for control of the illumination in examination of fields of vision in cases of chronic glaucoma would seem obvious; yet too little attention has been directed to it. The amount of light available should be recorded, whether

natural daylight or artificial illumination is used. The value of reduced light in demonstrating early field defects characteristic of glaucoma in what Traquair calls the preperimetric stage of the disease is suggested by the charts and the analysis of the cases studied. Ferree and Rand have used 7 foot candles in their perimeter and tangent screen, but in this study 0.02 foot candle was selected. (13 charts.)

Morano, M. **Glaucomatous changes of the lens.** *Boll. d'Ocul.*, 1946, v. 25, July-Sept., pp. 359-380. (See Section 9, Crystalline lens.)

Morano, M. **The physiologic action of prostigmin.** *Rassegna Ital. d'Ottal.*, July 1943-Dec. 1945, v. 12-14, pp. 468-503.

The author experimented with prostigmine intravenously and orally in normal and glaucomatous eyes. Administered parenterally, prostigmine causes miosis in normal eyes and in those in which adrenalin had been instilled, but has no effect upon atropinized eyes. The drug is effective especially in glaucoma complicated by vascular changes in the fundus, even in the post-thrombotic type.

The intravenous use of prostigmine lowers the general blood pressure, and, therefore that of the retinal circulation, and has proved beneficial in embolism of the central retinal artery. According to Morano a 1-percent solution of prostigmine is as equally effective as a 1-percent solution of eserine or 3-percent pilocarpine.

Moreu, Angel. **Experience with goniotrabeculotomy and gonioscyclothermy.** *Arch. de la Soc. Oft. Hisp.-Amer.*, 1946, v. 6, May, pp. 468-478.

The author thought that better results could be obtained in glaucoma by combining the cyclopuncture diathermy of Vogt and the goniotrabeculotomy of Barkan. Instead of using the Ziegler's knife he used a diathermic needle which is easier to manage. The scar left by this procedure is softer and more flexible, the hemorrhage is eliminated and the occurrence of infection is minimal. The operation can be repeated if it becomes necessary. A series of four cases is reported. From this study the author concludes that the proper selection of suitable cases is important. Eyes with absolute glaucoma and a narrow angle or with peripheral total synechia do not respond well. Glaucoma with wide angle and edematous zones of the ciliary body responds favorably. Intraocular hypertension follows the operation. This may last for 24 hours and is followed by lowering of the tension. It is not recommended to do more than six punctures, because sometimes it is necessary to operate again. The pupil must be in miosis and the use of miotics must be continued for the first 48 hours after the operation. Postoperative medical therapy is always necessary.

J. Wesley McKinney.

Moreu, Angel. **The mechanism of action of antiglaucomatous operations.** *Arch. de la Soc. Oft. Hisp.-Amer.*, 1946, v. 6, May, pp. 479-486.

The author states that there are antiglaucomatous operations which are very useful even though no fistulization is produced and the drainage is not increased. Such operations are iridectomy, cyclodialysis, diathermic punctures, gonioscyclothermy and goniotrabeculotomy. It has been proved many times by means of gonioscopy that iridectomy does not free the irido-corneal angle. The same results have

been obtained by performing sphincterectomy which conserves the iris root. The cyclodialysis does not make either a tunnel or a fistula. A short time after the operation is performed the tunnel is obliterated by a small blood clot and the ciliary body is firmly joined to the sclera which sometimes gives an evident peripheral synechia. Everybody agrees that diathermic punctures and gonioscyclodiathermy do not produce any drainage. Barkan says that goniotrabeculotomy would serve for opening the sclerosed wall of Schlemm's canal but the author repeats that in this type of operation the opening will close after a short period just as in cyclodialysis. Sometimes fistulization operations have been performed in which no filtration bleb has been observed. However, the tension of the glaucoma has been controlled. Undoubtedly these operations act upon glaucoma by a more complex mechanism than the mere establishment of drainage. The author agrees that all antiglaucomatous operations have a common mode of action; they act directly on the ciliary body by modifying its innervation or vascularization, and indirectly on the eyeball. He concludes that postoperative medical therapy is always necessary for the success of surgical treatment.

Thomassen. Thore Lie. Experimental investigations into the condi-

tions of tension in normal eyes and in simple glaucoma, particularly performed by subjecting the eyes to weight compressions. *Acta. Ophth.*, 1946, Supplement 27.

This monograph is a review of the literature on the effect of compression or massage on the normal and glaucomatous eye, and a report of an exhaustive experimental investigation. In this study compression was produced by Baillart's ophthalmo-dynamometer, placed on the limbus temporal to the cornea, and the tension measured by the Schiøtz tonometer, before compression, and 5, 15, and 35 minutes after compression. A compression of 25 gm. for 2 minutes, and of 150 gm. for 2 to 6 minutes was used in most experiments. During the compression there is a fall in tension, attributed to the forcing out of aqueous from the eye, through the canal of Schlemm. After the removal of compression the tension gradually returns to its initial level, and in some cases it continues to rise, producing a so-called relative hypertension. The latter is believed to be a reaction to the irritation of the compression, acting through the innervation of the ocular vessels, in the form of an increased blood volume, or an increased capillary tone with augmented secretion of aqueous. The result is an increased fluid content of the eyeball. The occurrence of relative hypertension in some eyes, and not in others, is explained by the varying faculty of eyes to compensate the effect of the compression. The extent of this power of compensation may be determined by finding the weight of compression required to produce a relative hypertension. The greater compression an eye can bear without producing a relative hypertension, the greater should be its power of compensation. The data show that

the power of compensation diminishes considerably with age, and is completely lost in glaucoma before the tension rises.

In this study all normal eyes withstood a compression of 150 gm. for 2 minutes without developing a relative hypertension, and this degree of compression is therefore taken as the minimum power of compensation for normal eyes. The extent of the fall in tension following compression varies, but is not affected by age. Homatropine reduces the fall during a compression, and pilocarpine increases it. Homatropine also reduces the compensating power of the eye, while pilocarpine augments it. In glaucomatous eyes the power of compensation is greatly reduced, and a relative hypertension may be produced by a compression of 25 gm. for 2 minutes; the result however, is greatly influenced by the phase of ocular tension during which the compression is performed. With compression performed in an increasing phase of ocular tension the fall in tension is small, and the relative hypertension high; in a decreasing phase of ocular tension the compression produces a marked fall in tension and no relative hypertension. This phenomenon was not discovered during former investigations, and accounts, the author believes, for the disparity of reported data. It is explained by the difference in the tension of the intrascleral veins. In an increasing phase of ocular tension, the tension in the intrascleral veins is high and the escape of fluid through Schlemm's canal is blocked. In a decreasing phase the tension in the intrascleral veins is low and the escape through Schlemm's canal becomes easy.

An attempt is made to apply the data obtained in this study to the clarification

of some of the glaucoma problems. The author finds that the data indicate that pathogenetically there are two forms of increased ocular tension. In one the tension rises as a result of a change in the ratio between the volume and the contents of the eyeball, such as is produced by pressing the eyelids together; in this form there is no increase in the tension of the ocular capillaries, and the rise in tension is compensated by the escape of aqueous through Schlemm's canal. The second form of increased intraocular pressure is due to a primary increase in the capillary tension, and can not be compensated by aqueous escape through Schlemm's canal. The increased ocular tension in glaucoma, as well as that produced by the provocative tests is of this type. Application of the data to the explanation of the regular oscillation in ocular tension suggests that the changes are due to corresponding changes in the tension of the ocular capillaries, stemming from rhythmical oscillations in a nervous impulse that originates in the central nervous system.

Clinically the use of compression as a provocative test is reliable only when it indicates an increased ocular tension. No fall in tension after compression is indicative of glaucoma. The occurrence of relative hypertension following compression of 25 gm. for 2 minutes is strongly suggestive of glaucoma. A relative hypertension following compression of 150 gm. for 2 minutes suggests the possibility of glaucoma. A negative test is of no value and carries no assurance of normal tension, because the test will also be negative in glaucoma in a decreasing phase of ocular tension. Compression may also be used as an aid in the evaluation of therapy. An eye with a poor power of

compensation should be kept under the influence of miotics even if the tension appears normal. Effective treatment with miotics should produce some power of compensation, and the compression test can be used to determine the required frequency of instillation of miotics. Compression with 25 gm. for 2 minutes is adequate for this test; if there is no relative hypertension after this compression, the therapeutic effect on the ocular tension can be regarded as satisfactory. CRYSTALLINE LENS

Cantonnet, F. Critical study of the incision in cataract extraction. *Ann. d'Ocul.*, 1946, v. 179, Dec., pp. 607-622.

The relative merits of cataract incisions made with the Graefe knife and keratome enlarged with scissors are analyzed in a series of 180 operations. The former was used in 106 cases, and the latter in 74. The complications which occurred at the time of incision are statistically analysed. The chief advantage of the keratome incision is that it can always be placed precisely in the limbus. Delayed healing occurred in 10 percent of the eyes opened with a Graefe knife and in four percent of those incised with a keratome. After six weeks the average amount of post-operative astigmatism as measured with a keratome was: Graefe, 3 diopters, keratome, 2 diopters.

Chas. A. Bahn.

Cristini, G. The fluorescence of normal and cataractous lenses. *Ophthalmologica*, 1947, v. 113, March, pp. 156-164.

Helmholtz was the first (1855) to observe and describe the phenomenon of fluorescence of the crystalline lens. The studies of F. P. Fischer (1934-1935) suggested a relationship between cataract formation and photolytic destruction of the so-called flavines of the lens substances related to vitamin B₂.

The fluorescence phenomenon seemed to be dependent upon the presence of those flavines. For that reason Cristini reinvestigated the fluorescence phenomenon. Cataractous human lenses obtained by intracapsular extraction or clear human lenses from eyes enucleated because of tumors of the sclera, were placed in the path of ultraviolet light obtained from an arc lamp; the rays transmitted and emitted by these lenses were analyzed qualitatively and quantitatively by means of a photometer. The behavior of clear and cataractous lenses was qualitatively the same: the lenses emitted a band of visible rays extending from 501 to 514 millimicrons. Brightness and saturation of this spectral band varied somewhat depending upon the type and stage of the cataract. Lens extracts prepared with water, methyl alcohol or chloroform, showed the same fluorescence phenomenon as whole lenses. These results indicated that the fluorescence of the lens was not dependent upon the physical arrangement of the particles within the lens but upon one or several chemical compounds, present both in clear and cataractous lenses. Exposure of the alkalinized extracts to large doses of ultraviolet light caused only a slight change of the fluorescence which proves that the substance causing the fluorescence is not a flavine, but probably a halloxazine substance. The question now arises: What is the relation of the latter substance to the respiratory enzyme system or to any of the metabolically important constituents of the lens?

Peter C. Kronfeld.

Johnstone, I. L. **Familial cataract with extensive pedigree chart.** *Brit. Jour. Ophth.*, 1947, v. 31, July, pp. 385-395.

Five generations of two branches of a family were studied with respect to a strongly persistent familial cataract. In all other respects the people studied were quite healthy and free from other developmental defects. Blood chemistry studies also showed no irregularities. One family branch consisted of 73 persons, 36 male and 37 female. The other branch included 58 persons, 28 male and 28 female (the sex of two members was unknown). Of these 58, 6 males and 11 females were affected. About 31 percent of the members were affected. Sex differences were insignificant. The disease was passed on by affected persons only and is therefore a Mendelian dominant characteristic.

The cataract itself was so characteristic that a person possessing it could be positively identified as a member of the family by examination of the eyes. It was a presenile, posterior, sub-capsular, saucer-shaped opacity which had leaf or feather-like radiations extending from its center, had flakes or dots of various colors, and caused an accentuation of the shagreen of the anterior capsule. It was always bilateral.

Knapp, Arnold. **Present state of the intracapsular cataract operation.** *Arch. of Ophth.*, 1947, v. 38, July, pp. 1-38.

This excellent paper combines a complete review of the literature and the author's opinions derived from his wide surgical experience. Anatomy, histology, techniques, accessory steps, instruments, complications, advantages and disadvantages are discussed in detail. (77 references.) R. W. Danielson.

Lee, O. S., Jr. **Corneoscleral suture in operations for cataract.** *Arch. of Ophth.*, 1947, v. 37, May, pp. 591-597.

The use of sutures for closure of incisions in cataract operations is one of the most useful and valuable refinements in ophthalmic surgery.

Ophthalmic surgeons do not all agree, however, that sutures aid in reducing the incidence of postoperative hemorrhage into the anterior chamber. Older writers were of the opinion that the bleeding came from the iris. More recent investigations, however, point to the incision as the source of hemorrhage. Any separation of the lips of the wound tears these vessels, and results in bleeding under the conjunctiva or, more frequently, into the anterior chamber.

For the past fifteen years it has been a routine procedure to employ three or more interrupted limbic-episcleral sutures for the closure of incisions in operations for cataract. In 1945 Lee and his associates began to use a modified Liegard suture placed in the 12 o'clock position on the limbus before the incision with the keratome was made, with two additional limbic-episcleral sutures placed on each side of it after extraction of the cataract. The use of this suture has reduced the incidence of hemorrhage into the anterior chamber in cataract extractions from 15.3 percent, when interrupted limbic-episcleral sutures alone were used, to only 6.6 percent, when the Liegard suture was added. When hemorrhages did occur, they were usually less extensive. (12 references, 1 illustration.) R. W. Danielson.

Morano, M. Glaucomatous changes of the lens. *Boll. d'Ocul.*, 1946, v. 25, July-Sept., pp. 359-380.

Lens changes are described in 14 eyes examined biomicroscopically in patients affected by glaucoma in its differ-

ent forms before and after antiglaucomatous surgical procedures had been performed. Aside from exfoliation of the anterior capsule and the acute subepithelial disseminated cataract of Vogt, a third kind of lens change was differentiated. This is the "glaucomatous cataract", which manifests itself as a posterior complicated cataract in primary glaucoma. One of the most important characteristics of the last type of cataract is the deterioration of vision after a surgical procedure. The writer advises examination of the lens with the slitlamp and dilatation of the pupil with adrenaline before attempting a decompressive operation so that the patient may be informed in cases of posterior complicated cataract that deterioration of vision may follow the operation. (Bibliography.)

Moretti, Ezio. Subluxation of the lens into the anterior chamber in the treatment of total congenital cataract. *Boll. d'Ocul.*, 1946, v. 25, July-Sept., pp. 402-406.

In the course of the dissection of a congenital hard cataract in an infant the capsule was not penetrated by the knife-needle but manipulation of the instrument provoked a partial luxation of the lens into the anterior chamber. The lens was absorbed some time later. It is assumed that in attempting to penetrate the capsule of the lens the zonula was broken and a tear in the posterior capsule was made through which the lens matter was absorbed by the aqueous. Because of the good result the procedure was purposely repeated in the other eye.

Melchior Lombardo.

Owens, W. C., and Hughes, W. F., Jr. Intraocular hemorrhage in cataract

extraction. Arch. of Ophth., 1947, v. 37, May, pp. 561-571.

The authors have reviewed 2,086 extractions of uncomplicated senile cataract performed at the Wilmer Ophthalmological Institute.

In order to determine what factors in the patient's general physical status might predispose to the occurrence of postoperative hemorrhage into the anterior chamber, the cases were analyzed from the following standpoints: (1) age, (2) blood pressure, (3) blood-clotting mechanisms, (4) diabetes, (5) syphilis and (6) foci of infection.

The authors concluded that except for severe diabetes, the general systemic condition of the patient is unrelated to postoperative hemorrhage into the anterior chamber. Operative techniques promoting firm closure and avascular healing of the incision reduced the incidence of this complication. These techniques include the use of two corneoscleral sutures and a shallow section. The visual results were significantly poorer in the eyes with postoperative hemorrhage into the anterior chamber than in those without hemorrhage. This was chiefly due to persistent opacities in the vitreous. (15 tables, 6 references.)

RETINA AND VITREOUS

Aguilar Muñoz, José. Recurrent edema of the macula (retinitis centralis serosa). Arch. de la Soc. Oft. Hisp.-Amer., 1946, v. 6, June, pp. 586-588.

A man 50 years of age had edema of the right macula three times within three years. On general examination only arterial hypertension was found and it was thought that the edema was due to the metabolic changes brought about by the arterial hypertension. In spite of the recurrence the outcome was favorable. J. Wesley McKinney.

Alvarz Luna, Rogelio. Berlin's edema and hole of the macula. Arch. de la Soc. Oft. Hisp.-Amer., 1947, v. 7, March, pp. 221-225.

The literature concerning the pathogenesis of Berlin's edema is briefly reviewed. A case of a young boy is reported, who suffered a traumatic injury to one of his eyes. The anterior chamber was completely filled with blood and when this disappeared the ocular fundus showed a small pigmented dot in the fovea, which diminished the vision to perception of hand movements at 20 cm. Later he developed a hole in the macula. J. Wesley McKinney.

Appelmans, M. Pseudo-albuminuric stellate retinopathy in a patient with paraganglioma. Arch. d'Ophth., 1946, v. 6, no. 4, pp. 448-455.

The author describes the case of a man, aged 30 years, who for six weeks had suffered from a great loss in vision. Ophthalmoscopic examination revealed a macular figure with hemorrhages and

edema of the nerve head and surrounding tissues. The arteries were contracted and the veins dilated. General examination revealed a hypertension and a slight albuminuria. Kidney function was normal but an abdominal tumor in the left upper quadrant was noted. Surgical removal yielded a heavily vascularized tumor situated under the renal hilus. Histopathologic examination revealed a non-encapsulated paraganglioma. Within a few days after removal of the tumor the hypertension had diminished, the vision was markedly improved, and the papilledema had disappeared. The macular star, however, persisted for several months. Vision returned to normal in each eye. Subsequently the tumor recurred and, in spite of radiotherapy, progressed. Six years after the surgical intervention the tumor had infiltrated widely although without metastasis. The retina showed no new involvement and visual acuity remained normal.

The author concludes that the pseudo-albuminuric retinopathy was the direct result of this endocrine tumor derived from embryonic sympathetic-system cells. The paroxysmal hypertension with intense headache and pulsation in the eyes was considered to be characteristic of hyperadrenalinism. The resultant angiospasm was assumed to be the cause of the retinal lesion because removal of the tumor caused disappearance of both the hypertension and the retinopathy. Phillips Thygeson.

Arcuri, D. Retinal detachment in pregnancy. Rassegna Ital. d'Ottal., July 1943-Dec. 1945, v. 12-14, pp. 275-300.

Three cases of retinal separation that occurred in the sixth, seventh and the eighth month of pregnancy are reported. Two were bilateral, and spon-

taneous reattachment took place in all three. The detachments persisted for from 12 to 20 days.

After thoroughly reviewing the literature the author points out the differences between the clinical picture, the pathogenesis, the course, prognosis and therapy in the separations in pregnancy and in the other forms. Although retinal reattachment occurs without treatment, the prognosis as to vision is not always good. Renal insufficiency of the mother is the most important cause. The detachment may be associated with acute or chronic nephritis and neuroretinitis. (5 colored pictures.)

Eugene M. Blake.

Barrenechea, S., and Contardo, R. Roentgen therapy of retinal venous thrombosis. *Arch. Chilenos de Oft.*, 1946, v. 2, July-Oct., pp. 235-241.

The cases reviewed by the author include eleven of thrombosis of a branch, and ten of thrombosis of the central vein of the retina. The etiology was usually arteriosclerosis and the age of the patients varied between 42 and 74 years. Fractional doses of X ray were used, reaching a total of 550 r in thrombosis of the central vein. The initial dose was 100 r. The cases are tabulated in detail, to support the authors' impression that X-ray treatment was beneficial. (References.)

W. H. Crisp.

Belmonte González, Nicholas. Retinal arteriovenous index. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1946, v. 6, May, pp. 442-445.

The diameter of the retinal arteries and veins is very difficult to measure and the percentage of error is very great. The author recommends finding the relation of the diameter between arteries and veins by means of the enlargement of the fundus picture. This

method permits the measurement of the vessels in tenths of millimeters. He found that normally the arteriovenous index is between 0.70 and 0.90. The application of this method is valuable for the early diagnosis and prognosis of hypertensive retinopathy. Several cases are reported with illustrations.

J. Wesley McKinney.

Belmonte González, Nicolas. A contribution to the study of experimental hypertensive retinopathy. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1947, v. 7, March, pp. 213-220.

This experimental work was done on dogs, whose fundi were carefully observed. Fifteen to eighteen months before the observations, the dogs had hypertension with a range between 160 and 200 mm. Hg, whereas 120 mm. is normal. They did not show alteration in the urine nor elevation of the urea in the blood. The disturbances observed in the fundus consisted of tortuosity of the vessels, disturbances at the arteriovenous crossing, thickening of the arterial walls and rarely hemorrhages. In the dog, an experimental chronic nephrogenous arterial hypertension produces a fundus picture similar to that of essential hypertension in man. Complete renal insufficiency provoked by bilateral nephrectomy does not produce elevation of the blood pressure, and does not give any retinal disturbance. The tightening of both ureters produces in the fundus the alterations of function necessary to produce angiospastic retinitis. (Colored illustrations.)

Campos, R. The respiration and glycolysis of the retina after section of the optic nerve. *Rassegna Ital. d'Ottal.*, 1947, v. 16, May-June, pp. 169-185.

The optic nerve of the rabbit was cut across within the orbit in a manner

which left the central retinal and long ciliary vessels intact. The respiration of the retina was then measured in Ring-er's solution by the Wardburg method, direct and indirect. In the same way the aerobic and anaerobic glycolysis was measured at various periods of time after the section of the nerve. Tests demonstrated that the metabolism of the retina maintains its characteristics even five months after the nerve has been cut. At this time the ganglion cells are completely degenerated, as shown by the histological study of the retina. (2 figures.) Eugene M. Blake.

Cerboni, F. C., and Malamud, B. Concerning three cases of asteroid bodies in the vitreous. *Arch. de Oft. de Buenos Aires*, 1946, v. 21, Aug., p. 213.

The authors present three cases of asteroid bodies in the vitreous. Two of the patients had normal vision and the other had senile lens opacities which lowered the visual acuity. There was no intraocular disease in any of the eyes. The condition is briefly discussed, with special emphasis on the differential diagnosis. (Illustrations, bibliography.) Plinio Montalván.

Dejean, C., and Laporte, P. Some clinical manifestations of tuberculous macular retinitis. *Arch. d'Ophth.*, 1946, v. 6, no. 4, pp. 397-412.

The authors describe four morphologic types of tuberculous involvement of the macula. The first type has been described under the name "solitary tubercle of the macula" and is characterized by cotton-wool exudates in the macular region. There is definite swelling associated with it. The condition persists for weeks and months and can develop into retinitis proliferans, or can become absorbed, leaving a large area of chorioretinal atrophy.

The second type, known as central

serous retinitis, is characterized by an intense macular edema, leading to the formation of a hemispheric bulla or a sort of serous cyst. The retinal vessels undergo a sharp bend when they reach the edge of the bulla. The evolution of this condition is described as being sluggish, often prolonged over several years and leading finally to an atrophy of the macula. It is often accompanied by vague ocular, orbital, and periorbital pain, tearing, and sometimes mild hypertony.

A third clinical type, known as brown macular retinitis, is not well known but is nevertheless of relatively frequent occurrence. It was noted particularly in prisoners of war returning from Germany. It is characterized by a brick red or brownish coloration of the macular region with an irregular and roughened appearance but with conservation of the foveal reflex. There is sometimes an alveolar appearance surrounding the fovea. The condition is described as evolving in four successive stages: (1) the brick red plaque stage, (2) the roughened brown plaque stage, (3) the brown alveoli or nodule stage, and (4) the black pigmentation stage.

The fourth type, known as radiating retinitis, is characterized by numerous whitish lines which diverge from the macula like the rays of the sun. The authors conclude that the ophthalmoscopic picture of this type is diagnostic.

The report is terminated by a discussion of etiology and therapy in which the authors express their regret that they were unable to control their studies by anatomical, bacteriological, and serological tests. They believe that a significant response to tuberculin therapy in these cases is evidence in favor of a tuberculous etiology.

The article is beautifully illustrated with eight drawings in color.

Jimenez Ruiz. *Retinitis proliferans and tuberculosis*. Arch. de la Soc. Oft. Hisp.-Amer., 1947, v. 7, March, pp. 226-233.

Two adult men had recurrent hemorrhages in the vitreous in the year before the examination. The fundus showed the classic picture of retinitis proliferans. The origin of the retinitis was said to be tuberculosis and in one of them Koch's bacillus was found in the sputum. J. Wesley McKinney.

Haridas, G. *Waren Tay-Sachs disease in a Chinese infant*. Brit. Jour. Ophth., 1947, v. 31, July, pp. 428-436.

This typical case of amaurotic family idiocy is presented because it is the first case of this disease ever observed in Malaya. Its occurrence in a non-Jew is of interest because it is widely believed that the disease is entirely racial. The infant, 13 months of age, was seen because of convulsions. Of his family history nothing could be learned since the parents never returned after the baby's admission. The child was blind, suffered progressive hydrocephalus, paralysis of all limbs and severe muscular wasting. Funduscopy revealed marked pallor of both discs and a purple-red macular spot on a milky white background in each eye. He died at the age of 20 months and 20 days of terminal lobar pneumonia. Autopsy report was not available.

Morris Kaplan.

Kettesy, A. *Technical improvements in the diathermy operation for detachment of the retina*. Brit. Jour. Ophth., 1947, v. 31, July, pp. 436-441.

The author expresses much dissatisfaction with the two types of coagulation treatment available. The perforating needle leaves the eye too soft and the sclera too wet for satisfactory tech-

nique and the Safar pins are awkward to hold in the forceps and are much too easily dislodged while further insertions are being made. He describes a new pin and forceps which has given him much satisfaction during the last three years. The pin is made of polished stainless steel with a round, flat head 0.3 mm. thick and 1.5 mm. in diameter. The length varies from 2 to 6 mm. It is cylindrical with a sharp conical point. The forceps is angular with grooves along three margins of the ends into which the pins fit securely. During the operation the pins are kept in flat cork plates. On a wood or plastic model of an eye made twice normal size, the procedures are sketched and planned carefully before each operation. The tear and the area of detachment are outlined. The longer pins, used for localization, are carefully watched with the ophthalmoscope and the shorter ones are used for the actual coagulation. (7 diagrams.) Morris Kaplan.

MacLean, A. L., and Brambel, C. E. *Dicumarol and rutin in retinal vascular disorders*. Amer. Jour. Ophth., 1947, v. 30, Sept., pp. 1093-1108. (1 table, 6 figures, 19 references.)

Magitot, A. *Clinical electrical retinography*. Ann. d'Ocul., 1947, v. 180, March, pp. 169-177.

The electroretinogram resembles the electrocardiogram in graphically electrically expressing organ function. The necessary apparatus consists of an illuminating and receiving-recording unit. The former includes an electric filament source, condensers, diaphragms, a rotary shutter, a tilted mirror, and a distance adjustment mechanism, all encased and suspended from a wall bracket. The recording unit consists of a contact glass electrode con-

nected by means of a head band, with a delicate galvanometer, and a recording drum.

The first phase in the electroretinogram is a slow component which corresponds with the initial current passage through the optic nerve. The second phase is more rapid and corresponds with rod and cone function. The third phase, like the first, is slow, and corresponds to the terminal current passage through the optic nerve. On the chart the first phase rises, the second is variable, and the third declines. The patient should remain in a dark room for thirty minutes before the E.R. is made. The lids are anesthesized by the Van Lint method and kept open with a blepharostat. In 92 of the 102 patients examined an electroretinogram was obtained on the first trial. Interpretation was difficult in approximately 20. An illumination of 20 lux and a stimulation time of $\frac{1}{25}$ second were adopted. The electroretinograms were arbitrarily divided into four groups. In the first group all phases of the graph were diminished; among the conditions observed were retinal detachments, pigment degenerations, and glaucomas. In the second group, the negative phase dominated the graph. Circulatory disturbances were more frequent in this group. In the third group all three phases were absent because there was no retinal function. In the fourth group all phases were equally subnormal. In several cases, a parallelism existed between the changes of the electroretinogram and the evolution of the disease.

Palomar Palomar, A. Anticoagulant medication (heparin, dicumarol) in the treatment of thrombosis of the retinal veins. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1947, v. 7, March, pp. 247-264.

Heparin was administered in four cases of thrombosis of the retinal veins, of which two involved the central vein and two one of its branches. Heparin was given intravenously in doses of 100 to 300 milligrams daily for 17 days. Dicumarol in doses of 100 to 200 milligrams was used orally, daily for 15 days, in eight cases of thrombosis of the central retinal veins and six in a branch. Improvement, only functional and not anatomic in some, was noted in all, especially where the medication was begun early. These drugs are contraindicated in hypertension, blood dyscrasias and icterus.

J. Wesley McKinney.

Plam, Erik. On the occurrence in the retina of conditions corresponding to the blood-brain barrier. *Acta Ophth.*, 1947, v. 25, pt. 1, pp. 29-35.

The findings in this laboratory study on seven rabbits confirmed the generally known incapacity of the retina to take vital staining with intravenously injected dyes, and its similarity to the central nervous system in that respect. The walls of the retinal vessels do not take the dye, which is in accord with the current opinion that the barrier to the passage of the dye in the central nervous system is formed by the vascular endothelium. The fact that the choroid which supplies nutrition to the outer layers of the retina, was found stained, whereas the retinal layers themselves did not take the stain, seems to indicate that the obstacle to the penetration of the dye in the retina must also be situated elsewhere than in the vascular wall. Louis Daily, Jr.

Wadensten, Lars. A case of bilateral non-attachment of the retina. *Acta Ophth.*, 1947, v. 25, pt. 1, pp. 61-71.

The patient, a seven-months-old in-

fant, one of premature biovum twins, was brought to the eye clinic with the history that she did not fix her gaze like her sister, and that the pupils shimmered gray. In each eye there was a white membrane with a suggestion of vessels pressed tightly against the posterior surface of the lens; the anterior chamber was shallow, and the iris and lens protruded. There was no pupillary reaction in the right eye, and it was enucleated. The detailed microscopic description shows a non-attachment of the retina, which was connected to the optic papilla by a cord of glial tissue. The literature contains about twenty reports of this congenital deformity, but only one case, that of Magnus, is analogous to the one here reported. The literature on the pathogenesis of this anomaly is reviewed. (3 photomicrographs.)

Louis Daily, Jr.

Walbeek, K. A case of degeneration of the macula lutea caused by central choroiditis. *Acta Ophth.*, 1947, v. 25, pt. 1, pp. 37-45.

A detailed clinical and histological description is given of an eye with a tumor-like mass in the macula which was enucleated because of hemorrhages and secondary glaucoma. The patient, a woman 40 years old, with a history of gall bladder disease, developed a central choroiditis in the left eye with vitreous opacities and involvement of the optic nerve. After five years she developed the tumor-like mass in the right eye, which was enucleated one year later. The histologic diagnosis was disciform macular degeneration. The literature on the etiology of this condition is reviewed, and it is argued that the history of a previous inflammatory process in the other eye supports the belief that the lesion is inflammatory, rather than vascular or degenerative in

origin. The site of the inflammatory process is in the choriocapillaris. (5 illustrations.)

OPTIC NERVE AND TOXIC AMBLYOPIAS

Caminero, G. M. Investigations on the pathogenesis of quinine amblyopia. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1947, v. 7, April, pp. 360-366.

Among the large number of malaria patients seen in North Africa in 1941 to 1943, Caminero found nine cases of quinine amblyopia. These patients were all seen early, and were all anemic people, with pale conjunctiva and dilated pupils. In addition to the usual symptoms, they had a diminished light sense, and delayed adaptation to light as well as darkness. They were followed for two years, and although they recovered their visual acuity, a constriction of the visual field remained. Caminero raises the question of a susceptibility to quinine amblyopia as a factor other than the toxicity of the drug itself. If such a factor exists, are there people sensitive to quinine, or does the malaria produce such a sensitization? Hemoglobinuric fever can be produced in malaria patients by the ingestion of very small quantities of quinine. Seeking to reveal the cause of this sensitization Caminero investigated the elimination of quinine in normal people and in malaria patients with and without quinine amblyopia. In normal individuals and in malaria patients quinine begins to be eliminated through the urine 25 minutes after ingestion, reaches the maximum after six hours, and is completely eliminated in three days. Of seven patients with quinine amblyopia the elimination was normal in three, somewhat delayed in two, and definitely delayed in two.

The total quantity of quinine eliminated was determined in only one case with amblyopia and found normal. Studies of kidney function failed to reveal any abnormalities. Ray K. Daily.

Kauntze, Ralph. Subacute bacterial endocarditis with onset as optic neuritis. *Brit. Heart. J.*, 1947, v. 9, Jan., pp. 34-37.

Two cases of subacute bacterial endocarditis are presented in the first of which there was retrobulbar neuritis at the onset and in the second bilateral papilloedema. Irwin E. Gaynon.

Leinfelder, P. J., and Robbie, W. A. Experimental studies in retrobulbar neuritis. *Amer. Jour. Ophth.*, 1947, v. 30, Sept., pp. 1135-1143. (8 tables, 16 references.)

Roussel, F., and Weekers, R. Changes of the critical flicker frequency in tobacco intoxication. *Ophthalmologica*, 1947, v. 113, April, pp. 215-223.

In a previous communication (*Ophthalmologica*, v. 112: 305, 1946) the authors described a method of measuring the critical flicker frequency of eccentric retinal areas and advocated the use of this method in the follow-up of diseases of the optic nerve. The paper under review deals specifically with cases of tobacco intoxication. The patients showed a lowering (slowing-down) of the critical flicker frequency in the region of the centrocecal scotoma, paralleling the latter in severity and extent. A slight lowering of the critical flicker frequency was found to persist after the visual field had returned to normal.

VISUAL TRACTS AND CENTERS

Beck, D. J. K. Upper parietal meningioma showing Foster-Kennedy syndrome. *Bristol Med. Chir. J.*, 1947, v. 64, Spring, pp. 11-12.

Whereas Kennedy stated that the syndrome associated with his name is a diagnostic criterion of the existence of an expanding lesion in the anterior fossa, this case illustrates the need to interpret the syndrome in the light of other signs and to pay attention to the stage at which the eye signs develop.

F. H. Haessler.

François, J. Binasal hemianopsia. *Ophthalmologica*, 1947, v. 113, June, pp. 321-343.

The author describes in detail two cases of neurinoma of the acoustic nerve and one case of opticochiasmatic arachnoiditis, all verified by operation and all showing chiefly binasal field defects. He compares the findings in his three cases with those in 49 similar surgically explored or pathologically examined cases from the literature. He also reviews the anatomy of the region of the chiasma. He concludes that the main mechanism concerned in the causation of binasal hemianopsia is a disturbance of the normal spatial relationship between the supero-temporal aspect of the optic nerves and the anterior cerebral arteries. The arteries may press against the nerves or the nerves may be crowded against the arteries. (11 figures.)

Peter C. Kronfeld.

Nichelatti, Paolo. Adie's syndrome in hysteric subject. *Boll. d'Ocul.*, 1946, v. 25, July-Sept., pp. 421-432.

A nun, 42 years of age, when in-

formed that her left pupil was larger than the right, complained of neuralgic pains of the left side of her face and photophobia, and her vision became reduced to 2/10 in each eye. Left pupillary reactions were as slow in normal daylight as in the dark. Her left pupil was enlarged when the patient was kept in a dark room for about an hour and became contracted when the patient was exposed to intense light for an hour. Consensual and accommodation reactions were also slow. The diagnosis was based on these changes of the left pupil, on the lack of deep reflexes, and the negative serologic examinations. The other ocular disturbances were hysteric in nature and disappeared under appropriate treatment. (Bibliography.) Melchior Lombardo.

13

EYEBALL AND ORBIT

Casanovas, José. **Orbital osteomas.** *Arch. de la Soc. Oft. Hisp.-Amer.*, 1947, v. 7, April, pp. 335-347.

A review of the literature, and brief reports of six cases are presented. Two patients had growths in a sinus, two of the tumors arose from the orbital walls with a broad base, and two tumors were pedunculated. In one case osteoma was bilateral. In two patients the exophthalmos almost caused ocular dislocation. Five cases were dealt with surgically. Histologic examination showed that two of the tumors consisted of compact bone, and three were spongy. (8 illustrations.)

EYELIDS AND LACRIMAL APPARATUS

Busacca, A. **A simple and easy method of blepharoplasty.** *Ann d'Ocul.*, 1947, v. 180, May, pp. 288-292.

Disinsertion of the external palpebral ligament facilitates marked displacement of the upper and lower lids. Greater advancement of the skin to cover traumatic or other colobomas is thus possible. Following local anesthesia and the administration of coagulin, venine, or other coagulating agents, external canthotomy to the orbital rim is performed. A subcutaneous vertical incision about one-fourth inch in the external palpebral ligament is made. The coloboma is freed of cicatricial tissue. A cutaneous incision is made roughly parallel to the upper or lower lid border and extending from the coloboma margin almost to the orbital rim. The skin is undermined to form a flap. The edges of the coloboma are approximated by a mattress suture horizontally placed, and the lid flap is drawn over the coloboma laterally and sutured. The canthotomy wound edges are approximated by laterally advancing, with a suture, the skin of the upper or lower lid approximately one-half inch. (11 figures.) Chas. A. Bahn.

Dollfus, M. A. **The irradiation treatment of the lid epitheliomas.** Report presented at the meeting of the Société d'Ophthalmologie de Paris, 1946, Nov., 160 pp.

The extensive research work on the irradiation treatment of lid epitheliomas carried on by the author and his collaborators at the Foundation Curie from 1927 to 1940 is reported.

The first part deals with the history, pathology and clinical manifestations of lid epithelioma, and the differential diagnosis from chronic ulcerative blepharitis, tuberculous and syphilitic lesions, and nevocarcinoma, is described.

The second part—the physical properties of radio-active substances in general, the characteristics of the different rays, and the occurrence and potential dangers of secondary radiation are discussed. The units of radium element and radium emanation, the Curie, are described in detail.

Other points of importance in the specification of every radium application are the shape and size of the carriers, their number, the kind and density of the primary and secondary filters, the positions and the distance between carriers and irradiated tissue, the strength of the carrier, the time of irradiation in hours, the energy as expressed in the units described, and the surface and depth extension of the irradiated tissue. A plastic material of beeswax 100 gm., paraffin 100 gm., and fine sawdust 25 mg. is molded on the face in varying thickness depending on the distance required for the irradiation. Radium needles in four different strengths and lengths, tubes, and gold seeds containing 1 to 2 millicuri radon are used for the contact treatment. A mixed irradiation treatment, namely surface irradiation plus curie-puncture, was used in infiltrating cancers.

The third part deals with X-ray treatment. The origin and peculiarities of X rays, the importance of the different filters, the irradiation with single large or divided small doses, and the results and dangers of this treatment are described in detail. The doses for circumscribed lesions vary from 2000 to 5000 r, most frequently 2600 to 3600 r. For extensive lesions 5000 r were given.

The maximal doses were 9600 r. The exact dosage is important because of the dangers of an insufficient treatment which not only might cause a radio-resistance, but might also change the clinical form of the epithelioma to a more malignant type.

The contact-therapy of Chaoul, a comparatively new method in the irradiation of lid epithelioma is discussed. The principle of this method is the surface utilization of rays which penetrate but little and rapidly decrease in effect in the sub-epithelial layers. Their range is only two centimeters of surface diameter and one of depth range, which limits their general use but coincides with the average size of lid epithelioma.

Part four summarizes the pre-radiation care and immediate effects of the irradiation on the epithelioma. Part five contains the reports of the results and the failures of those treatments. The potential danger of ocular complication makes necessary a close collaboration of radiologists and ophthalmologists during every stage of the irradiation. The after care is especially important as patients with lid epithelioma have to continue in constant supervision for at least three years. Recurrences usually appear during this time.

In part six the author discusses the ocular complications and the means to avoid them. The improved methods, as well as the use of metal, especially lead shells in the form of a prosthesis over the eyeball, have reduced the frequency of complications, but the latter can never be completely avoided. Early complications are mostly benign, late complications mostly insidious and of uncertain prognosis. Common complications are hyposecretion of the lacrimal glands, interstitial keratitis, corneal necrosis, iridocyclitis, secondary glaucoma, and opacities of the lens.

Young lenses are especially vulnerable. Degenerations of the retinal and choroideal vessels as sequelae of irradiations are rare.

In part seven the results of irradiation treatment are compared with the results of diathermy and surgical treatment. This comparison is not complete because of the lack of adequate reports concerning the late results of surgical treatment. A table shows the results of radium and X-ray treatment during the last 25 years. (379 references, 5 tables.)

Godtfredsen, Erik. Relation between Sjögren's disease, the Plummer-Vinson syndrome, and ariboflavinosis. *Acta Ophth.*, 1947, v. 25, pt. 1, pp. 95-109.

The literature on the three syndromes is reviewed, and their interrelation analyzed in the hope of throwing some light on the etiology and pathogenesis of Sjögren's syndrome. In addition a report is made of an analysis of 23 cases of Sjögren's syndrome col-

lected since 1943 from the Ophthalmic Departments of the County Hospital, Gentofte, The Finsen Institute, and the State Hospital in Copenhagen. The patients were all women in the postmenopausal period. Twenty patients had chronic progressive polyarthritis. The articular affection had persisted from 1 to 30 years before the affliction was recognized as Sjögren's syndrome. The Plummer-Vinson syndrome, the most characteristic features of which are epithelial lesions in the upper alimentary tract and sideropenia, formed a part of the pathologic picture in three patients. All had greatly reduced or completely abolished lacrimal secretion, and most of them were treated for about five years with irritative instillations before the diagnosis of keratoconjunctivitis sicca was made. None had the superficial vascularization characteristic of ariboflavinosis. Treatment with viatmine B and iron relieved the alimentary tract symptoms in the three patients with Plummer-Vinson syndrome but in the others it was entirely ineffective. Sideropenia or riboflavin deficiency appear to have no etiologic significance in Sjögren's diseases, and in spite of the numerous common clinical features, it is concluded that Sjögren's disease differs essentially from ariboflavinosis and the Plummer-Vinson syndrome.

TUMORS

Casanovas, Jose. Orbital osteomas. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1947, v. 7, April, pp. 335-347. (See Section 13, Eyeball and orbit.)

Höhr Castán, Jose. Ocular xeroderma pigmentosum. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1946, v. 6, May, pp. 487-491.

A boy, 10 years of age, had a small whitish tumor mass, a xeroderma pigmentosum, on the lumbus of the left cornea for one and a half years. The patient also had several plaques of xeroderma pigmentosum in the cervical

and sternal zones. All other examinations were negative.

J. Wesley McKinney.

Huggert, A., and Hultquist, G. T. True glioma of the retina. *Ophthalmologica*, 1947, v. 113, April, pp. 193-202.

Only two cases of true retinal glioma consisting almost exclusively of adult glial cells have been reported, one by Dejean and one by McLean (*Arch. of Ophth.* 18:255). One new case is put on record in the paper under review. A male patient, age 77 years, presented himself at the eye clinic of the Caroline Hospital, Stockholm, with the complaint of gradual deterioration of the vision of the left eye for several years and pain and inflammation for the last two weeks. The eye was found to be in a state of absolute glaucoma. A yellowish mass, resembling a hypernephroma, filled the entire anterior chamber. During the enucleation the conjunctiva and Tenon's capsule were found to be indurated and difficult to detach. Hard yellowish masses occupied the inferior and nasal portions of the orbit. In places these masses had disintegrated into curd-like material. A tumor mass filled the interior of the globe almost completely; it had destroyed or replaced the retina and had invaded the optic nerve. The choroid was torn in several places but not thickened, the sclera appeared uninvolved.

Histologic examination showed that the tumor consisted chiefly of polymorphous cells with honeycombed, vacuolated cytoplasm. Silver impregnation revealed numerous argentophilic cells with a few short, scantily branched processes. In most places, the tumor was compact in structure with sparse bands of connective tissue between the cell masses. Pseudo-rosettes around blood vessels could be seen in moder-

ate numbers. The description is not clear with regard to the amount of necrosis, but its presence in the center of groups of tumor cells is mentioned. There was an abundance of mitotic figures and, as mentioned before, definite polymorphism of the nuclei. The authors classify the tumor as a true retinal glioma of the oligodendroglioma type. The extraocular masses are thought to be metastases. No statement is made about the postoperative course and termination of the disease.

Peter C. Kronfeld.

Hughes, L. W., and Ambrose, A. Massive melanosa of the eye. *Arch. of Ophth.*, 1947, v. 38, July, pp. 111-112.

This case is recorded not so much for its pathologic interest, because the tumor is one of the common ones affecting the eye, but because of its spectacular size. A photograph of this far advanced tumor is given. Paradoxically, two years after evisceration of the orbit the patient shows no recurrence.

R. W. Danielson.

Garcia Miranda A. Fibroma of the orbit. *Ophthalmologica*, 1947, v. 113, March, pp. 149-156.

A white male, 25 years of age, complained of slowly increasing protrusion of his left eye of about seven years' duration. Examination revealed a palpable hard tumor in the upper temporal portion of the left orbit. Roentgenologic findings were normal. The tumor was removed by the Kroenlein technique. It was well circumscribed and located outside the muscle cone. Its place of origin could not be ascertained. The histologic examination revealed a fibroblastic tumor consisting mainly of spindle-shaped cells in a criss-cross but

not truly fascicular arrangement. There was an abundance of heavy collagenous and of finer reticulin-like fibers. The author considers the tumor to be benign and of mesodermal origin, but is not entirely certain of his diagnosis because of the abundance of cellular elements. The main features of the tumor are shown in three good photomicrographs. There apparently was no opportunity for postoperative follow-up.

Peter C. Kronfeld.

Pfeiffer, R. L. Tumors of the eye and orbit. *N.Y. Acad. Med. Bull.*, 1947, v. 23, July, pp. 410-419.

The author describes the clinical manifestations of naevus, precancerous melanosis, malignant melanoma, retinoblastoma, lymphatoid disease involving the eye, granuloma, neurofibromatosis, cholesteatoma, and adrenal neuroblastoma.

INJURIES

Adler, F. H., Fry, W. E., and Leopold, I. H. Pathologic study of ocular lesions due to lewisite (β -chlorovinyl-dichloroarsine). *Arch. of Ophth.*, 1947, v. 38, July, pp. 89-108.

The pathologic changes in the rabbit eye injured by lewisite are described. In the early stages changes appeared in the stroma which may be interpreted as a rapidly progressing necrosis of the whole stromal layer. This was seen in the loss of the nuclei of the corneal fibers, the loss of staining ability of these fibers and their loss of outline. These changes were first seen at the end of six hours and reached the maximum in 24 hours. The infiltration of the stroma began at the periphery at the 24-hour stage and was of poly-

morphonuclear cell type. This infiltrate was replaced by a round cell infiltrate at the end of the 10-day stage. Vascularization did not make its appearance until the end of five days. This vascularization involved all layers of the stroma but was most prominent in the middle layers. In 14 days the vascularization was fairly intense. In any eye treated with BAL there were no changes that could be attributed specifically to the treatment. The changes were similar to those observed in the untreated eye but were of milder degree. (15 figures.)

R. W. Danielson.

Atkinson, W. S. Exact surface localization of ophthalmoscopically visible foreign bodies in the vitreous chamber. *Arch. of Ophth.*, 1947, v. 38, July, p. 110.

Small foreign bodies in the vitreous chamber which are entangled in the retina and choroid or embedded in the sclera are often not pulled loose with the magnet unless it is applied close to or directly over the foreign body. In order to make the incision exactly at the point where the foreign body can be seen, a Walker retinal detachment pin is first inserted as a pilot as close to the area as possible. The incision is then adjusted according to the relative positions of the foreign body and the pin.

R. W. Danielson.

Marin Amat, M. A case of a foreign body imbedded in the external layers of the sclera. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1947, April, pp. 375-379.

Marin Amat reports an industrial injury, in a man 26 years old, whose right eye was perforated through the cornea by a foreign body, which was found by X-ray examination. Misleading yellow-

ish conglomerations were present in the lens, and on the retina. Attempts at extraction were unsuccessful, and the eyeball, greatly traumatized by these procedures, was finally enucleated. Histologic examination showed a fusiform, irregular, sharp piece of iron encysted in the outer layers of the sclera.

Rones, B., and Wilder, H. C. Nonperforating ocular injuries in soldiers. *Amer. Jour. Ophth.*, 1947, v. 30, Sept., pp. 1143-1160. (25 figures, 3 tables.)

Savin, L. H. The effect of aluminium and its alloys on the eye: a report presented to the vision committee of the medical research council. *Brit. Jour. Ophth.*, 1947, v. 31, Aug., pp. 449-502.

This comprehensive study is based on two clinical observations and extensive experimental work.

The author reviews the literature and presents two cases of intraocular aluminium foreign bodies. In each instance the fragment became coated and left multiple imprints due to shifting position before disintegrating into white powder after many months. Good vision was retained in one case.

For experimental study 34 intraocular implants were made. It was found that the ocular reaction was more severe with higher amounts, but there was no clinical difference between pure aluminium and various alloys. Both groups showed lens opacities, mild inflammatory changes in the iris, atrophy of the iris, retinitis proliferans and vascularization of various parts of the eye. Aluminium causes more destruction in the vitreous than in the anterior chamber. Early changes, chiefly vascular, occurred in tissues adjacent to the foreign bodies.

Fundus lesions showing widespread distribution of the aluminium in the tissues were present in nearly every case, no matter what the size or position of the implant. In six eyes there was apparently complete dissolution of the aluminium, but the author was unable regularly to obtain specific stains of the section to be sure of the true distribution in the ocular tissues.

Also noted in the experimental animals were bullous keratitis, staphylococcal keratitis, zonular keratitis, interstitial and deep keratitis, pigmented cornea and folds in Descemet's membrane.

Aluminium had previously been regarded as comparatively inert in the eye. The author has conclusively shown that it causes widespread low-grade inflammatory and degenerative changes, seen histologically as well as clinically. Although aluminium and its alloys are not so destructive as iron and steel, these intraocular foreign bodies call for operative removal.

There is a graphic summary in which the findings in the eyes of the animals are made perspicuous by diagrammatic drawings. (21 figures of which 9 are in color.)

O. H. Ellis.

Sorsby, A., Haythorne, J., and Reed, H. Further experience with amniotic membrane grafts in caustic burns of the eye. *Brit. Jour. Ophth.*, 1947, v. 31, July, pp. 409-418.

This is a report of additional experience of the use of human amniotic membrane in chemical burns of the eye. In these severe burns, the eyes were generally found to be nearly white in 3 to 5 days after grafting and they were usually normal by the end of the week. Now 28 additional cases are reported, 21 of burns by lime, 5 by sodium hydroxide and 2 by fireworks. Corneas

were involved in all, and yet in only three eyes was the vision unsatisfactory. Terminal clarity of corneas was directly related to the interval between injury and treatment. The amniotic membrane is apparently tissue specific in its action. It does not lead to clarification of severe corneal damage but it does prevent corneal damage caused by a persistent raw conjunctiva. The details of preparing the amnion for grafting are described. Morris Kaplan.

Tanzariello, R. The tolerance of the eye to aluminum and its alloys. *Rassegna Ital. d'Ottol.*, 1947, v. 16, May-June, pp. 199-223.

Small pieces of aluminum and of various commercial compounds containing aluminum were introduced into the vitreous chamber of rabbits' eyes. The foreign bodies were retained from 10 to 187 days and the eyes were observed frequently with the ophthalmoscope. One of the compounds contained 90 percent of copper and this was as poorly tolerated as pure copper. Other compounds, with only 3.5 percent copper were much better tolerated. Pure aluminum caused practically no reaction. The author concludes that when intraocular foreign bodies of alloys of aluminum enter the eye, those which contain copper demand early efforts at removal, whereas pure aluminum may safely be followed for long periods. SYSTEMIC DISEASES AND PARASITES

Casari, G. F. Ocular manifestations of erythema nodosa. *Rassegna Ital. d'Ottol.* 1947, v. 16, May-June, pp. 228-250.

The ocular manifestations of erythe-

ma nodosa are analogous to the lesions elsewhere. The picture is that of an allergic reaction, which may be homo-allergic, heteroallergic or para-allergic. The last named seems the most satisfactory explanation. Some cases are especially difficult to classify. The eye manifestations are particularly important because they may be isolated instances of the disease or may precede the manifestation in the skin and mucous membranes. Three cases are reported in which ocular lesions that had the appearance of phlyctenules complicated the general eruption. The literature is reviewed and a bibliography appended.

E. M. Blake.

Cordello, G. Ocular symptoms in subarachnoid hemorrhage. *Rassegna Ital. d'Ottal.*, 1947, v. 16, Jan.-Feb., pp. 50-63.

Subarachnoid hemorrhage may be a result of a general disease, such as infection, liver damage, blood disease or an intoxication. The source of the bleeding is either a ruptured aneurysm (frequently the result of congenitally defective structure of the vessel) or functional vasoneurotic disturbance, often endocrine in origin.

The ocular manifestations are disturbances of the motor nerves, changes in the optic nerves, particularly edema, retinal hemorrhages, and a group of symptoms, such as nystagmus, verbal blindness, violent retrobulbar pain, and loss of sight.

Three cases are reported in detail.

Eugene M. Blake.

Dekking, H. M. Tropical nutritional amblyopia ("camp eyes"). *Ophthalmologica*, 1947, v. 113, Feb., pp. 65-92.

"Nature, that most unscrupulous vivisectionist, has just finished one of her

greatest experiments, a war. Of all her vast laboratories, the South East Asia theater of war has yielded some very remarkable results from an ophthalmologic standpoint. Hundreds of thousands of men, women and children have been kept in cages for almost four years, and have been subjected to all kinds of deficient diets and to incredible physical and mental strains." Under these circumstances, which the author has well described and hardly exaggerated, a tropical nutritional amblyopia (called "camp eyes" by the Dutch physicians) has occurred on a much more extensive scale than ever before. Striking features of the disease are its occurrence in the concentration camps of South East Asia and not of Germany and its predilection for adult males of light complexion. Among women the disease is so rare that "in many women's camps not even the name (of the disease) was known." The onset is usually gradual, with bilateral irregular paracentral scotomas, nyctalopia and a tingling or burning sensation in the feet and legs. The author has not seen the earliest stages, but other physicians have reported congestion of the retinal vessels and small retinal hemorrhages in some of the patients (percentage not known). In the late stages the maculae may be slightly abnormal and the temporal halves of the discs are pale. The prognosis is bad. Adequate food plus supportive measures continued for periods of eight months and longer have not brought about any improvement.

While in the concentration camps the patients' food consisted of red or white rice and a very diluted vegetable soup. Thus, there existed a deficiency of all vitamins as well as of animal proteins and of fat. The author discusses all likely causes of the amblyopia and ar-

rives at the conclusion that the disease "cannot be ascribed to one single agent, but that it is most probably due to gross deficiency of B vitamins, plus an intoxication (tobacco?), plus, perhaps the intense tropical sunlight as an aggravating factor." Peter C. Kronfeld.

Grant, W. T. **Complete removal of craniopharyngioma with recovery from blindness.** Bull. Los Angeles Neurol. Soc., 1947, v. 12, March, pp. 53-58.

A two-year-old Mexican boy had complete blindness for three weeks which began 12 days after a head injury. The optic discs were normal. The left pupil responded to light two days after the extirpation of a craniopharyngioma and the child was able to see on the seventh day. Irwin E. Gaynon.

Rugg-Gunn, A. **A case of recurrent aphthous uveitis with associated ulcer vulvae actum.** (Lipschütz). Brit. Jour. Ophth., 1947, v. 31, July, pp. 396-409.

Aphthous uveitis is a new and rather rare clinical entity which presents three main groups of symptoms. These are a periodically recurring uveitis, skin eruptions which consist of macular pustules that resemble those of secondary lues and recurrent erythema nodosum, and aphthous ulcers in the mouth and genitals. The eye-symptoms appear late, though once established, progress rapidly toward deterioration and blindness. The etiology is unknown and it is particularly characterized by its resistance to any known treatment.

The author reports his observations of a woman, 22 years of age, who had recurrent uveitis, in alternating eyes, for over a year before other signs developed. Although she was resistant to several regimens of therapy she reacted best to intravenous protein. During the

year it was felt that the infection was tuberculous. Buccal aphthae then appeared, followed by a severe aphthous ulcer of the vulva. The left eye progressed to blindness whereas the aphthous lesions apparently healed spontaneously during the latter months of a normal pregnancy. The skin lesions did not appear at all. The author insists that all signs point to a virus as the causative agent. (5 diagrams.)

Morris Kaplan.

Sanchez Mosquera, M. **Ocular cysticercus.** Arch. de la Soc. Oft. Hisp.-Amer., 1947, v. 7, March, pp. 234-246.

A man, 40 years of age, had noted defective vision in his right eye for three weeks. There was a gray haze, aching, and a burning sensation of the eye. Ophthalmoscopic examination showed a brilliant gray-blue perfectly spherical cyst in the optic nerve head which contained a tapeworm scolex complete with hooks and four suction discs. The cysticercus moved about constantly. *Tenia saginata* was also found in the feces. The cysticercus was removed after some attempts to kill it by means of radium applications and sulfanilamides. (Photographs.)

J. Wesley McKinney.

Schmidt, A. E., and von Albertini, A. **The ocular vessels in endangiitis obliterans** (von Winiwarter-Buerger). Ophthalmologica, 1947, v. 113, March, pp. 129-148.

Marchesani was the first ophthalmologist (1932) who considered endangiitis obliterans as the cause of vascular ocular diseases such as retinal periphlebitis, recurrent vitreous hemorrhages with the associated uveitis, retinal vascular spasms, embolisms, and thromboses. Marchesani's view did not

become generally accepted. A. E. Schmid, one of the authors of the paper under review, in a previous publication (*Ophthalmologica*, 110:259, 1945) denied any relationship between endangiitis obliterans and retinal periphlebitis. The present study deals with the part played by Buerger's disease in spastic and occlusive diseases of the retinal vessels.

The pathology of the endangiitis process is described and illustrated. The earliest change is a transient fibrinous inflammation of the intima, followed by a chronic stage in which the arterial or arteriolar wall undergoes sickle-shaped thickening due to deposition of "fibrinoid" masses which gradually increase in thickness through additional fibrinoid deposition but also through organization and, later on, lipoid infiltration. The latter, however, is always a secondary process in contradistinction to the primary degenerative arteriosclerosis which is not a lumen-reducing disease. The preferred sites of endangiitis obliterans are the vessels of the lower extremities, the coronary arteries, the aorta and the cerebral arteries. The angiitic disease may cause secondary arterial occlusion distal to the specific lesion or secondary ("additional") thrombosis next to it; it may also be responsible for spastic aggravation of the existing vascular disease.

The findings in a number of cases studied pathologically by the authors supported by a critical survey of the literature leads them to the conclusion that ocular involvement is very rare in endangiitis obliterans. If ocular involvement does occur, it is secondary to localization of the disease in the carotid artery or its branches. In most of these cases the ocular involvement has been in the form of conjugate deviation,

hemianopic scotomas, transient visual disturbances, transient diplopia, cortical blindness or papilledema. True intraocular vascular disturbances, such as arterial spasm, embolism or thromboses, have been extremely rare. In all these eye manifestations the primary site of the disease is in the carotid or its branches. Retinal hemorrhages may occur, but can always be distinguished from those of retinal periphlebitis which, the authors maintain, is unrelated to endangiitis obliterans.

Amer. Jour. Ophth., 1947, v. 30, Sept., pp. 1073-1080.

Grant, W. M. Students' model for slit lamp biomicroscopy of the aqueous humor. Arch. of Ophth., 1947, v. 38, July, p. 109.

For familiarizing students with the biomicroscopic appearance of the normal and the abnormal aqueous humor a series of model eyes is of considerable value. The type of model which the author has found satisfactory in post-graduate teaching has a convex glass "cornea," a rubber "iris" and a glass "lens," with an "anterior chamber" which can be filled with various artificial "aqueous humors." The construction is described.

The following aqueous preparations have been found satisfactory. Distilled water simulates normal aqueous in that it gives the appearance of an "optically empty" anterior chamber. Diluted plasma with protein concentrations of 0.2 and 2 percent presents different intensities of the Tyndall effect. A dilute suspension of red blood cells in isotonic solution of sodium chloride, a suspension of cholesterol crystals, and a suspension of diatomaceous earth show the thermal convection currents.

MISCELLANEOUS

GIVES OPHTHALMIC BOOKS

Dr. Frederick W. Adams, formerly of Seattle, Washington, and now of Carmel, California, has presented his collection of books on ophthalmology to the new medical school of the University of Washington. The bound volumes number 215, and there are many unbound journals. Since his retirement, Dr. Adams has been a frequent exhibitor in the Physicians Art Association.

RARE GLASGOW JOURNAL FOR SALE

A copy of the *Glasgow Medical Journal*, dated 1829, bound in cloth and leather, is available for purchase. This is an historical item of great rarity and of great interest to ophthalmologists because it contains three classical articles by the pioneer eye surgeon, William Mackenzie, one time lecturer on the eye in Glasgow University. The price has been set at \$50.00. Anyone interested may communicate with the Ophthalmic Publishing Company, 700 North Michigan Avenue, Chicago 11, Illinois.

BETTER VISION INSTITUTE MEETS

The Better Vision Institute held its third quarterly meeting in New York City on October 3rd. M. J. Julian, president of the Institute, gave a visual presentation and detailed descriptions of recent, current, and future projects.

Of immediate interest to professional members was the new series of 24 scientific leaflets just off the press. These leaflets are rich in information on practically all aspects of vision. For example, the leaflet entitled *Eyes on the Jump* deals with the process of reading and the value of professional guidance in improving reading habits. *Fit for Your Eyes* highlights the important duties of the ophthalmic dispenser and explains how his precise art can supply each individual with the glasses which will most help his appearance as well as his vision. *Learning to See* discusses the development of "seeing gaits" in people, and how good or bad ones may be acquired just as different walking gaits are ac-

quired. Thank you B. F. is the scientific story of Franklin's contribution to human progress in the invention of bifocal lenses.

Other subjects covered in these leaflets range from the new telescope on Mount Palomar to heredity as it applies to eyes. But all topics are treated in a scientific manner, and the need for regular professional eye-care is consistently emphasized. The series of leaflets will be distributed to Institute members, and through them to schools, museums, and other educational centers.

Mr. Julian gave an outline presentation of the new set of educational charts which are being developed. These will comprise pictorial lessons on the human eye and how it sees, light and its relation to vision, color and color perception, lenses and how they bend light, faults of seeing, eye tests, and seeing skills. The charts will conclude with an "Eye-Q" quiz on a wide variety of visual themes.

Plans were also sketched for the Institute's general educational work during 1948. The meeting's guest speaker was Dr. Jules Backman, associate professor of economics at New York University.

NEW BROCHURE READY

The Bausch & Lomb Industrial Vision Department announces that a new brochure for the ophthalmic profession is now available. Entitled *Ortho-Rater Scores and Clinical Examinations*, the booklet, Bulletin A-608, is designed to fill a need for correlating the Ortho-Rater scores with the clinical approach.

This timely brochure, produced in answer to professional requests for an explanation of the Ortho-Rater-clinical relationship, was held until comprehensive studies on the subject had been developed.

Requests for Bulletin A-608 may be made by letter or post card to the Industrial Vision Department, Bausch & Lomb Optical Co., Rochester, New York.

SOCIETIES

READING HAS 69TH MEETING

The 69th meeting of the Reading Eye, Ear, Nose, and Throat Society was addressed by Dr. Gabriel Farrell, director of Perkins Institute and Massachusetts School for the Blind, Watertown, Massachusetts. The subject of his talk was "Modern Trends in Education of the Blind."

BROOKLYN MEETING

The Brooklyn Ophthalmological Society held its 101st regular meeting on October 23rd. The scientific program included a paper by Dr. Algernon B. Reese on "Discussion of Some Controversial Aspects of Ocular Tumors," and one by Dr. Alson E. Braley on "Virus Diseases of the Cornea." Dr. Mortimer A. Lasky presented a case report on "Progressive Essential Atrophy of the Iris." Dr. Leonard Posner was elected to membership.

MILWAUKEE SOCIETY PROGRAM

Dr. John G. Bellows, Chicago, was a guest speaker at the October 28th meeting of the Milwaukee Oto-Ophthalmic Society. His subject was "Use of Antibiotics in Ophthalmology: With Special Reference to Streptomycin." Dr. Emil Rothstein spoke on "Streptomycin in Otolaryngology."

NEW SOCIETY ORGANIZED

The newly organized Los Angeles Ophthalmological Society has elected the following officers: Dr. Orwyn Ellis, chairman, and Dr. John A. Bullis, secretary. The society meets at 6:30 p.m. on the third Tuesday of each month from September through June. The meeting place is at 3550 Wilshire Boulevard.

ANNOUNCEMENTS

RESERVATIONS FOR HAVANA MEETING

All those who are planning to attend the III Pan-American Congress of Ophthalmology in Havana, Cuba, January 4 to 10, 1948, *and have not already done so*, should send their inscription fee of ten dollars together with a deposit for a room (ten dollars) to Dr. Miguel A. Branly, Edificio Bacardi 70, Piso, Havana, Cuba, at the earliest possible moment. Those who have confirmed reservations in the hotels will have no need to fear that their reservations will be cancelled.

SCHOENBERG MEMORIAL LECTURE

The first annual Mark J. Schoenberg Memorial Lecture will be held at the New York Academy of Medicine at 8 p.m., December 1st, under the joint sponsorship of the New York Society for Clinical Ophthalmology and the National Society for the Prevention of Blindness. The speaker of the evening will be Dr. Peter C. Kronfeld, of Chicago, head of the Illinois Eye and Ear Infirmary, whose subject will be "The Canal of Schlemm."

This lectureship was established as a memorial to Dr. Schoenberg's interest and original work in the control of glaucoma.

PERSONALS

GOOD-WILL LECTURE, TOUR

Dr. Daniel B. Kirby, New York, returned recently from a good-will lecture and conference tour of South America. Under the auspices of the Pan-American Association of Ophthalmology, Dr. Kirby visited Rio de Janeiro and São Paulo, Brazil; Montevideo, Uruguay; Buenos Aires, Rosario, and Cordoba, Argentina; Santiago, Chile; and Lima, Peru. Dr. Kirby reports that the South American oculists are very cordial and that many of them plan to attend the III Pan-American Congress in Havana and to visit the United States either before or after the Congress.

ADDRESSES OKLAHOMA MEETING

Dr. C. Wilbur Rucker of the Mayo Clinic, Rochester, Minnesota, was a guest speaker at the 17th annual meeting of the Oklahoma City Clinical Society, October 27th to 30th.

GUEST SPEAKER AT UTAH

Dr. A. Ray Irvine of Los Angeles spoke at the 52nd meeting of the Utah State Medical Association at Salt Lake City.

INTRODUCTION

Pityrosporum ovale, a yeastlike fungus as yet unclassified, was first described in 1874 by Malassez¹ who considered it to be the cause of seborrheic dermatitis. Although *P. ovale* is constantly present in this disease, there is still a difference of opinion among dermatologists as to whether its role is pathogenic or purely saprophytic. Etiologic studies have been handicapped by the fact that pure cultures of *P. ovale* have been obtained only with great difficulty, and by the fact that no experimental animal has been shown to be truly susceptible to seborrheic dermatitis. A number of inoculation experiments on human beings have been reported but the results have always been in doubt because of the possibility of error in the identification of the organism and in the interpretation of the induced skin lesions.

* Presented at the 16th scientific meeting of the Association for Research in Ophthalmology, Inc., Atlantic City, June, 1947. This study was made possible by a grant from the Berthold Guggenheimer Donation.

[†] From the Department of Bacteriology, University of Pennsylvania Medical School.

[‡] From the Division of Ophthalmology, University of California Medical School, San Francisco.

Seborrheic dermatitis, whose major localization is the scalp (seborrhea capitis, pityriasis capitis), has long been known to affect the eyebrows and eyelids, seborrheic blepharitis being one of the principal types of lid-margin infection. In 1938, Kile and Engman² reported finding varying numbers of *P. ovale* in scrapings from the lid margins of 21 of a series of 24 patients with blepharitis. In many instances large numbers of the organism were seen, even in the presence of secondary pyogenic infection. Nearly every one of these patients also had pityriasis of the scalp. As a result of numerous attempts to cultivate *P. ovale* from the lid margins of each of 10 of these patients, cultivation was obtained in three. Scales from the eyelids of six patients were used to inoculate excoriations on the chest. In two instances there were positive reactions consisting of scaliness, slight erythema, and a subsequent browning of the skin. The lid margins of five rabbits were rubbed with *P. ovale* culture without result.

In 1945, one of us (P. T.)³ reported finding *P. ovale* in a high percentage of scrapings from cases of blepharitis and noted the close correlation between the

clinical manifestations of seborrheic blepharitis and the demonstration of the organism. He suggested that lid-margin scrapings were of value in the diagnosis of seborrheic blepharitis and of even greater value, as a guide to therapy, in evaluating the importance of the seborrheic factor in cases showing pyogenic infection.

The present study was undertaken in an attempt to cast further light on the role of *P. ovale* in seborrheic blepharitis and in the conjunctivitis and keratitis which sometimes accompany it. It is concerned with the morphology of the organism, its cultivation, its frequency in external inflammations of the eye, and its pathogenicity for man and animals.

ISOLATION OF *P. OVALE*

All reports in the literature indicate that *P. ovale* is extremely difficult to cultivate. Since it does not have absolutely distinctive morphologic characteristics and fails to produce specific lesions on animal inoculation, it has been difficult to prove that fungi isolated from the scales of seborrheic dermatitis were indeed *P. ovale*. Benham⁴ has recently reported the cultivation of the organism and has defined its cultural characteristics. From her work it would seem that identification of the organism in culture is based essentially on its microscopic morphology, on its colony appearance and rate of growth, and, most importantly, on its lipophilic properties.

METHOD

In the studies reported here, the following media were employed: (1) Sabaraud's dextrose agar (Difco), (2) wort agar (Difco), and (3) wort agar plus 1.5-percent oleic acid. The dehydrated wort agar was used in a concentration of 6 percent instead of the 5 percent recommended by the manufacturer, because the latter produced too soft a

medium after the addition of oleic acid.

Cultures from blepharitis subjects were made by removing the macroscopic scales from the lids with a sterile platinum wire or spatula and introducing them directly to the surface of the agar plate. After the scales had been removed, the lids were rubbed with a sterile cotton swab which was then streaked onto the unused portion of the agar plate. In the cases in which no scales were evident, the swab method only was employed. Plates were sealed with wide rubber bands, incubated at 37°C., and examined daily for growth. As soon as any colony growth whatever appeared which resembled *P. ovale* microscopically, the colony was streaked out on the plate with a wire loop. A more luxuriant growth was thus obtained in a shorter time than would otherwise have been possible.

Cultures of dandruff were made by having the patient brush his hair with his fingers over an exposed plate. The plates were incubated at 37°C. and when growth first appeared on the scales, or around them, it was streaked out.

From cases of seborrheic dermatitis, scales were obtained with a platinum loop or spatula and implanted directly onto the surface of the culture plate.

Isolation from blepharitis. A total of 24 cases of blepharitis showing yeastlike bodies suggesting *P. ovale* in lid-margin scrapings were studied for the presence of *P. ovale*. On Sabaraud's medium, which was used in 16 of the 24 cases, staphylococci were recovered invariably and in several instances there were also other cocci and Gram-positive rods. On this medium, staphylococci, although not abundant, were by no means inhibited. A yeast which was not *P. ovale* was isolated from one case. Contaminating molds were not uncommon.

On wort agar, which was used in all 24 cases, Gram-positive cocci were found

in a few cases and yeasts in four. No *P. ovale* were isolated. Contaminating molds, particularly *Penicillium*, *Aspergillus*, and *Alternaria*, were common.

Wort agar containing 1.5-percent oleic acid was also used in all 24 cases. No bacteria grew on this medium, but yeasts were isolated from six cases. Molds were uncommon although their rapid overgrowth in three cases necessitated the discarding of plates. Organisms believed to be *P. ovale* were isolated from five cases, that is, 5 out of 24, or 21 percent. Three of these isolations were subcultured and maintained through several generations. The other two were never successfully isolated in pure culture and were lost due to contaminating molds. The first colonies of the organism appeared in from 4 to 7 days.

In a subsequent culture study made in San Francisco, *P. ovale* was isolated in pure culture on wort agar containing oleic acid from 1 of 5 cases of seborrheic blepharitis from which isolation was attempted and has been maintained in pure culture through 10 transfers.

Isolation from dandruff (pityriasis capitis). Six cases of dandruff, in which *P. ovale*-like organisms were readily demonstrable by microscopic examination of the scales, were cultured on wort agar containing oleic acid. Isolation of the organism was accomplished in 4 of the 6 cases.

Isolation from seborrheic dermatitis. *P. ovale*-like organisms were found in the epidermal scales of three patients with seborrheic dermatitis of the face. The scales were removed and planted on wort agar containing oleic acid. Typical *P. ovale* were isolated from all three cases.

PROPERTIES OF *P. OVALE*

The following criteria were used for the identification of the organism in this study: (1) Microscopic morphology,

which included typical bottle forms as described in the literature. (2) Colony morphology; that is, the slow-growing colonies of typical appearance and color as described by Benham.⁴ (3) Lipophilic properties as determined by (a) failure to grow either in primary isolation or in subculture in media not containing oleic acid but readiness to grow in media containing it, and (b) growth characteristics in Benham's synthetic medium.⁵ This is a clear aqueous solution of inorganic salts and glucose to which oleic acid is added. The lipophilic organisms produce an opacity of the oil globules, by growing in and around them, and leave the aqueous portion clear. Nonlipophilic organisms produce a marked turbidity in the aqueous portion and the oil globules remain clear and translucent. (4) Confirmation of the isolation (3 cases) by Dr. Rhoda Benham of Columbia University.

The cultural characteristics of the organisms isolated in this series coincided with those described by other workers, including Benham⁴ and Moore and associates.⁶ The bottle or flask-shaped forms were typical and characteristic. While these forms predominated in cultures, other forms were also found, including dumb-bell shaped, elongated, oval, lemon-shaped, pear-shaped, and budding forms. The size of the oval and elongated forms varied from 2 to 7 microns in length and from 1½ to 2½ microns in width. The organisms had a definite tendency to form clumps.

The first colonies appeared in from 4 to 7 days after inoculation but subcultures grew more rapidly, colonies appearing in from 2 to 5 days. A cheesy odor was characteristic. Typical colonies were small (½ mm. in diameter), convex, granular, feather-edged, and light tan in color. The color darkened with age and the oily surface characteristic of young colonies became dry and powdery. Aging also pro-

duced corrugation and wrinkling of the colony which became hard, brittle, compact, and impossible to emulsify. On subculture, giant colonies as large as 12 mm. in diameter developed after two weeks' growth. Some strains became nonviable after multiple subcultures but three strains survived 15 subcultures. These three were sent to New York to Dr. Rhoda Benham who reported that they were identical with the strains of *P. ovale* isolated by her.

P. OVALE IN LID-MARGIN SCRAPINGS

Figure 1 illustrates the usual appearance of the organism in lid-margin scrapings. There was considerable variation in morphology, but spherical cells, both large and small, and often with budding, were the most common forms. Flask or

bottle forms, so common on the scalp, were rarely seen in preparations from the lid margin. The smallest cell observed was about 2 microns in diameter and the largest about 11 microns. It was noted on repeated examination that in the same individual there would be a preponderance of spherical budding forms on the lid margins and a preponderance of oval and flask-shaped forms on the scalp. In a certain number of cases, however, almost 100 percent of the forms on the lid margins were flask-shaped. No clear relationship between the type of clinical blepharitis and the preponderance of either spherical or oval forms was apparent. Moore and his associates,⁶ on the other hand, stated that small, ovoid, budding forms were characteristic of acute, rapidly spreading infections, that both ovoid and spherical cells were seen in active

subacute infections, and that in chronic or quiescent lesions many large, thick-walled, resting cells, as well as both ovoid and spherical cells, were to be found.

In this study budding yeast forms morphologically like *P. ovale* were found in 100 percent of 143 cases of clinically typical seborrheic blepharitis. As previously reported by one of us, typical seborrheic blepharitis (fig. 2) is squamous in type, with large, greasy scales, and is associated with seborrheic dermatitis of the scalp and often of the brows. While this is the more common form, the disease may also appear as a squamous blepharitis with dry, small scales and hyperemic lid margins. Excluded from this study were a considerable number

Fig. 1 (Gots, Thygeson, and Waisman). *Pityrosporum ovale* in lid-margin scrapings from a case of typical seborrheic blepharitis. Giemsa stain. (Magnification $\times 2,400$.)

of cases complicated by pathogenic staphylococci.

The organisms were most numerous in scrapings from those portions of the lid margins which showed the greatest inflammation and, as also reported by Moore and associates,⁶ they were almost always present in the upper portion of the hair follicles of the cilia. They could be seen adhering to the shafts of cilia removed and examined microscopically.

The effect of therapy upon the organism in lid-margin scrapings was significant. The customary treatment for seborrheic blepharitis has been twice-weekly applications of silver nitrate to the lid margins and twice-daily applications of an ointment consisting of 1-percent ammoniated mercury and 1-percent salicylic acid in petrolatum. Under this treatment there was rapid disappearance of the organisms from scrapings, but if treatment was interrupted prematurely for any length of time, the organisms inevitably recurred. Moreover, when apparently healed cases suffered recurrences, *P. ovale* invariably reappeared in lid margin scrapings.

Treatment with 5-percent sulfathiazole ointment or penicillin ointment alone did not significantly affect the number of *P. ovale* in scrapings. This paralleled the lack of therapeutic effect of these two preparations on pure seborrheic blepharitis.

SENSITIZATION TO *P. OVALE* EXTRACT

An extract of *P. ovale* culture, prepared according to the method employed in the preparation of trichophytin,⁷ was used for sensitivity studies in 46 individuals suffering from seborrheic blepharitis in which *P. ovale* was demonstrated in scrapings. All cases also had scalp infection of one degree of severity or another. The test was made by the injection

of 0.1 cc. of the extract intradermally into the skin of the forearm or upper arm. Readings were made in one hour and again in 24 and 48 hours. No immediate reactions of significance were noted and only 5 of the 46 individuals showed delayed reactions believed to be significant. In these there was a tuberculinlike reaction and in two of the cases the area of erythema was six inches or more in diameter. Of these five positive cases, three had severe seborrheic blepharitis with severe conjunctivitis and keratitis. These were the only severe cases in the entire group of 46 individuals tested for skin sensitivity.

Sixteen individuals without seborrheic blepharitis, and without obvious scalp infection or history of seborrheic dermatitis, were also tested. In these there were no significant reactions, immediate or delayed.

ANIMAL AND HUMAN EXPERIMENTATION

ANIMAL SUBJECTS

Transmission experiments with scrapings from seborrheic blepharitis. A search of the literature disclosed no record of the production of a typical seborrheic dermatitis or blepharitis in animals with scrapings from the human disease, and no record of the occurrence of the disease spontaneously in animals. In a rather wide experience with laboratory animals, including monkeys, apes, dogs, guinea pigs, rabbits, rats, and mice, we do not recall ever having seen any skin lesion suggestive of seborrheic dermatitis or blepharitis. It seemed worthwhile, however, to attempt transmission of the disease with scrapings from seborrheic blepharitis. For this purpose 12 cases were chosen in which *P. ovale* was present in large numbers in the epithelial scrapings. Inoculation by light scarifica-

tion with a platinum spatula was made directly from the lesions. The skin, lid margins, and conjunctivas were inoculated simultaneously in a total of 18 rabbits and 21 guinea pigs. In no instance did an infection resembling seborrheic dermatitis result. A mild, self-limited, scaly dermatitis of short duration developed in five rabbits but could not be considered significant. Except for transient hyperemia of the conjunctiva after inoculation, no conjunctival changes were noted in either rabbits or guinea pigs.

Transmission experiments with P. ovale culture. Skin. Two rabbits were inoculated by rubbing *P. ovale* organisms, obtained from heavy agar-plate growth, into a scarified area on one side of each rabbit. As a control the other side was inoculated similarly with a nonpathogenic yeast (*Saccharomyces*).

RABBIT 1. There was nothing of note until the sixth day when a definite scalliness appeared on the side inoculated with *P. ovale*. The control side also tended toward scalliness but the scales were firm and intact in contrast to the loose, flaky scales on the side inoculated with *P. ovale*. Methylene-blue mounts of these scales were negative and no organisms were obtained from them in culture. Examinations were made periodically. The scalliness persisted and on the 14th day, scales which were cultured yielded an organism which was at first thought to be *P. ovale*. The similarity was striking but further studies showed that it was not *P. ovale* as it grew readily in the absence of fats and developed mycelia. The scaly condition disappeared spontaneously and on the 24th day the rabbit appeared to be normal.

RABBIT 2. There was nothing of note until the sixth day when a thick, brownish yellow encrustation developed at the site

of the *P. ovale* inoculation. The appearance of this lesion corresponded with the description of the lesions on rabbits given by Moore and associates.⁶ The control site presented a few fine, thin crusts which were not as heavy nor as thick as those on the inoculated side and may well have been due to the scabbing over induced by the scarification. The crusts from the side inoculated with *P. ovale* were removed and *P. ovale* forms were found in methylene-blue mounts and were grown successfully in culture. In this experiment there was no doubt as to the organism's identity. The crustlike appearance rapidly disappeared and on the 10th day was replaced by a flaky, loose scalliness. No organisms were demonstrated in these scales nor isolated in culture. By the 19th day the area appeared normal. No spreading occurred.

In an effort to determine the effect of scarification alone, the skin was scarified as before but no organisms were introduced. A slight scalliness with a few fine crusts appeared. This lesion was comparable to that produced by the control inoculation of Rabbit 2. No loose, flaky scalliness developed.

Thirty days after the inoculation of Rabbit 2, identical inoculations were made at the same sites. The reactions were the same as in the first experiments and *P. ovale* forms were found in the scales. There was no evidence of sensitivity to the previous inoculation. No positive cultures were obtained, but in this connection it should be borne in mind that the culturing of the rabbit scales was extremely difficult due to the profusion of contaminating molds; the one positive culture obtained in the first experiment was barely saved. Before the second inoculations were made the skin of one of the areas was rubbed with oleic acid. This was done to see if the "take" would be

better. The oleic acid had no apparent effect on the type or degree of response.

Eye. The upper lid of the eye of a rabbit was rubbed with growth from a culture of *P. ovale*. A control yeast was rubbed on the lid of the other eye. No changes occurred until the ninth day when a macroscopic scaliness appeared along the margin of the lid inoculated with *P. ovale*. Scrapings from this lesion showed many *P. ovale* forms and identical forms were demonstrated continuously in scrapings taken on the 11th, 19th, and 21st days. No organisms were found in scrapings from the control eye. Scrapings from the six eyelids of three normal rabbits were also negative. In no instance was *P. ovale* isolated in culture. The scaliness diminished gradually but was still evident after 34 days. No spreading occurred. In comparison with the conjunctiva of the control eye, the conjunctiva of the eye inoculated with *P. ovale* was mildly hyperemic.

Ear. *P. ovale* were also inoculated directly, without scarification, onto the ear of a rabbit, and a control yeast onto the other ear. A flaky, loose scaliness developed on the 10th day on the ear inoculated with *P. ovale*. The control side presented a scaliness which was firm and intact. Examination of normal rabbits' ears revealed the same type of firm, intact, scaly surface. Scales from the *P. ovale* side were loose and profuse, particularly in the area of inoculation. No spreading occurred. *P. ovale*-like organisms were readily demonstrated in methylene-blue mounts but no positive cultures were obtained. The scaliness disappeared spontaneously after the third week.

The same place on the same ear was again inoculated 30 days after the first inoculation. Again a loose, flaky scaliness appeared but this time there was also a marked erythema which may possibly

have been a manifestation of sensitivity produced by the previous inoculation.

HUMAN SUBJECTS

Strips of gauze containing growth from a culture of *P. ovale* were placed on the backs of two human volunteers and left in situ for 24 hours.

Patient 1. Results negative after one week.

Patient 2. On the fifth day an area of dry erythema and dry superficial scaling was evident. The lesion did not resemble typical seborrheic dermatitis. The area affected corresponded closely to the application site. No spreading occurred in three days. *P. ovale*-like organisms were found in methylene-blue mounts of scales. No cultures were made.

OTHER YEASTLIKE ORGANISMS FROM BLEPHARITIS

A total of 11 yeastlike organisms, other than *P. ovale*, were isolated from 8 of the 24 cases of blepharitis subjected to culture study. These all appeared similar microscopically and culturally. The colony growth was white and pasty, turning tan and brown with age. There was a typical yeasty odor. Growth occurred readily on Sabaraud's medium, wort agar, and blood-agar plates. In Benham's synthetic medium⁵ growth occurred in the aqueous component, the oil globules remaining clear. Microscopic examination revealed a preponderance of oval forms. Growth first appeared in from 2 to 7 days. After two weeks giant colonies of four strains developed the characteristic "eruption" surface due to gas formation. No ascospores were demonstrated on carrot media. Mycelium formation was studied on corn-meal agar by slide-culture technique. Seven of the strains formed mycelia. These were considered to be members of the *Monilia*-*Mycotorula*

group, and the four which did not produce mycelia to be members of the *Cryptococcus* group. No further identification could be made.

The occurrence of these yeasts in lid-margin cultures raises the question of the identification of *P. ovale* in lid margin scrapings. Can other yeasts simulate *P. ovale*? In an effort to clarify this point, the correlation between the appearance of *P. ovale*-like forms in lid-margin scrapings and the growth of yeasts on Sabaraud's medium, wort agar, and blood-agar plates, was studied in a series of 12 cases. All ordinary yeasts grow readily on these media and, if present in any numbers on the lid margin, would make profuse growth on culture. This was not the case, however, since never more than two or three colonies of yeast developed on these media from any one of the dozen cases, even though yeastlike forms were numerous in scrapings. It is our belief, therefore, that the sporadic yeasts isolated were air-borne contaminants.

DISCUSSION

In looking for a relationship which might be analogous to that of *P. ovale* in seborrheic blepharitis and its secondary conjunctivitis and keratitis, one inevitably turns to a consideration of the role of *Corynebacterium xerosis* in xerophthalmia. It will be recalled that the xerosis bacillus, found constantly in xerophthalmia, was originally described as the cause of the disease. Attempts to reproduce xerophthalmia with pure cultures of the diphtheroid invariably failed, however, and the disease was eventually shown to be due to avitaminosis A. Is it possible that *P. ovale* may play the same saprophytic role in seborrheic blepharitis?

According to the evidence available, the following important differences seem to obtain: (1) Seborrheic dermatitis, unlike xerophthalmia, is almost undoubtedly in-

fectious even though there is as yet no positive proof; (2) *P. ovale*, unlike *C. xerosis*, is not entirely devoid of pathogenicity for animals; and (3) *C. xerosis* is a saprophyte which will grow on almost any medium; whereas *P. ovale*, like many pathogens, is fastidious in its growth requirements. As a matter of fact, it is extremely difficult to isolate *P. ovale* and maintain it in pure culture as it is unable to grow in the absence of lipids. Its growth requirements would be more readily supplied by a parasitic existence via the naturally occurring fatty acids. For these reasons it seems unlikely that *P. ovale* could play a purely saprophytic role.

Etiologic studies in seborrheic dermatitis have been made extremely difficult by the lack of a suitable experimental animal. To our knowledge the direct transmission of seborrheic dermatitis to animals has not been obtained and certainly no one has ever produced with lid-margin scrapings the clinical picture of seborrheic blepharitis and its associated conjunctivitis and keratitis. Even human inoculations have not been entirely satisfactory. Thus it would seem to be almost impossible to fulfill Koch's postulates in this disease.

If Koch's postulates cannot be fulfilled, what are the possibilities for determining etiology? If *P. ovale* is the etiologic agent it should satisfy the following conditions: (1) It should produce the same results in animal and human inoculation experiments as are obtainable with tissue from seborrheic dermatitis. (2) It should be found consistently in the lesions of the disease. (3) It should be absent, unless a carrier state should exist, from the healed lesions.

As reported in this study, *P. ovale* produced a mild dermatitis and conjunctivitis in the rabbit comparable to that produced by scrapings from seborrheic blepharitis;

it was found consistently in the lesions of the disease; and, with a few exceptions only, it was absent in clinically normal lids. The demonstration of skin sensitivity to *P. ovale* extract in certain individuals indicates, moreover, that the organism produces inflammation irrespective of its role in seborrheic dermatitis.

Noteworthy in this study was the occurrence, in rare instances, of a very severe conjunctivitis and keratitis in association with seborrheic blepharitis. Eight such cases are reported and in each *P. ovale* was present in enormous numbers in lid-margin scrapings (fig. 3) and in lesser numbers in the conjunctival secretion (fig. 4). In these cases there were no demonstrable pathogenic staphylococci or other pathogens. The occurrence of a skin reaction to *P. ovale* extract in the three cases tested was significant and suggests the possibility that the conjunctival and corneal lesions were allergic in nature.

Therapeutic studies in seborrheic blepharitis yielded data of interest in connection with *P. ovale*. In the 56 cases in which lid margin scrapings were examined repeatedly during the course of treatment, there was a definite correlation between clinical improvement and reduction in the number of *P. ovale*. When the disease recurred in patients who had been rendered symptom free by therapy, there was invariably a recurrence of *P. ovale* in the scrapings.

SUMMARY AND CONCLUSIONS

1. Seborrheic dermatitis of the eyelids is a common external disease. Ordinarily mild and almost symptomless when not secondarily infected, the disease in its pure form is occasionally associated with a severe conjunctivitis and keratitis. The only constant bacteriological finding in the disease is the presence of *Pityrosporum ovale*.

2. First described in 1874, this as yet unclassified yeastlike organism has been incompletely studied and its role in seborrheic dermatitis remains unsettled. Clinical seborrheic dermatitis does not occur naturally in animals and animal

Fig. 4 (Gots, Thygeson, and Waisman). *Pityrosporum ovale* in conjunctival exudate from a case of severe seborrheic blepharitis with associated conjunctivitis and keratitis. Giemsa stain (Magnification $\times 1,150$).

inoculations with *P. ovale* have failed to reproduce the disease. The few human inoculations recorded have been inconclusive. Difficulties concerned with the isolation of the organism in pure culture and with the recognition of the experimental disease make it impossible to determine on the basis of published reports whether the organism occurs in the lesions of seborrheic dermatitis as a saprophyte or is concerned etiologically.

3. The occurrence of *P. ovale* in scrapings from 100 percent of 143 cases of clinically recognizable seborrheic dermatitis of the eyebrows and eyelids is reported. The organism was isolated in pure culture with difficulty and only on media containing fatty acid, such as oleic-acid-

wort-agar medium. In scrapings the organisms usually appeared in moderate numbers in mild cases and in enormous numbers in severe cases.

4. The morphologic and cultural aspects of the organism isolated from seborrheic blepharitis are described in detail. It is noted that round forms were more common in lid-margin scrapings than in scrapings from infected scalps.

5. Animal and human inoculations with cultures of *P. ovale*, or with lid margin scrapings from seborrheic blepharitis, produced temporary inflammations from which the organism could be isolated, but failed to reproduce the clinical signs of seborrheic dermatitis.

6. Intradermal injections of *P. ovale* extract in 16 individuals without gross seborrheic blepharitis or dermatitis of the scalp produced questionable or negative reactions; in 5 of 46 individuals with seborrheic dermatitis of the eyelids, on the other hand, the injections produced

significant skin reactions. Three of the five showed severe conjunctival and corneal lesions. This suggests the possibility that sensitization may be a factor, particularly in the production of corneal lesions.

7. The present study provided no conclusive evidence that *P. ovale* was pathogenic for the eye and its adnexa but the following findings were suggestive of an etiologic relationship; (1) The constant occurrence of the organism in the lesions; (2) the apparent relationship between the number of organisms present in scrapings and the severity of the clinical disease; (3) the absence of the organism, or its exceptional presence in small numbers only, in clinically normal eyes; (4) the inability of the organism, unlike most saprophytes, to grow on any but complex media; and (5) the demonstration, by intradermal skin tests, of sensitization to the organism.

CONJUNCTIVITIS WITH MEMBRANE FORMATION*

MICHAEL J. HOGAN, M.D.
San Francisco, California

It is intended to present: (1) A classification of cases of conjunctivitis which develop membranes; (2) the pathogenesis of membrane formation which accompanies conjunctivitis; (3) case reports of typical examples of membranous conjunctivitis; (4) studies on the pathogenicity of corynebacteria recovered from diseased conjunctivas.

I. CLASSIFICATION OF CONJUNCTIVITIS EXHIBITING MEMBRANES

1. Bacterial

a. Acute diphtheritic

Acute streptococcic

Acute pneumococcic

Acute meningococcic

Acute gonococcic

Acute Koch-Weeks

Acute *Bacillus coli*

Acute *B. faecalis alcaligenes*

Acute *B. dysenteriae*

Acute Vincent's

b. Chronic streptococcic

Chronic tuberculous

2. Due to viruses

Acute herpes febrilis

Acute epidemic keratoconjunctivitis

Acute vaccinal

Acute inclusion blennorrhea

3. Due to higher plant parasites

Chronic thrush

Chronic streptothrix

4. Toxic

Acute—in erythema multiforme

Acute—in pemphigus

5. Allergic

Acute (transient)—in vernal catarrh

6. Traumatic

7. Chemical

8. Due to unknown or uncertain causes

Chronic ligneous

II. PATHOGENESIS OF MEMBRANE FORMATION ON THE CONJUNCTIVA

Membrane formation on the conjunctiva may result from a variety of local infectious, allergic, or traumatic lesions. At times it occurs in conjunction with constitutional diseases, or becomes apparent as a result of a general toxemia. Considerable investigative work has been performed to elucidate the nature of membrane formation.¹⁻⁶ It is now well known that the conjunctiva reacts to injuries with the frequent production of membranous lesions. The membrane formation is characteristic in some diseases. This mucosal reaction depends upon the tissue itself, and the duration of action, and concentration of the causative agent. There is ample evidence that the membrane which accompanies infectious diseases is formed exactly as the membrane which follows chemical injuries.² Some agents which are fairly toxic at first produce a light membrane; if their action continues an adherent membrane is formed. Occasional bacteria, such as the diphtheria bacillus, may produce either a catarrhal,^{3, 7, 8} pseudomembranous, or membranous conjunctivitis.

The objective appearance of membranes has caused them to be classified into two main groups: (1) Pseudomembranes, and (2) true membranes.

Pseudomembranes are produced by the coagulation of a fibrinous exudate on the inner surface of the conjunctival epithe-

* From the Institute of Ophthalmology, Presbyterian Hospital, Columbia University, and the Proctor Foundation for Ophthalmology, Division of Ophthalmology, University of California Medical School. Presented at the 16th scientific meeting of the Association for Research in Ophthalmology, Inc., Atlantic City, June, 1947.

lium. Numerous leukocytes, red blood cells, and desquamating epithelial cells are found enmeshed in the fibrin. There is no close connection between this coagulated fibrin and the underlying tissues, so it is easily removed. It should be emphasized that in some diseases, such as inclusion blennorrhea and vernal catarrh these pseudomembranes are frequently transient in duration and seldom recur. At other times, they are more permanent, tend to recur soon after removal, and persist until the toxic agent has been overcome by the tissues. Still others may be of long duration, recurrent in type, and resistant to therapy.

True membranous conjunctivitis is characterized by a massive exudation of fibrin and albuminous fluid into the epithelium and superficial substantia propria. This exudate is also coagulated on the inner surface of the epithelium. In those cases following a milder course, this persists and the membrane undergoes lysis or may be removed with complete healing. More severe cases are characterized by necrosis and the whole membrane may be sloughed off, leaving a raw bleeding surface. The surface may again become covered with a membrane. As the tissues overcome the infection, the membrane ceases to form and new epithelium covers the raw surface. In the most severe cases, toxins or chemicals may produce widespread vascular damage with thrombosis. As a result, considerable sloughing of the conjunctiva may occur with subsequent formation of adhesions between the lids and globe.

III. CASE REPORTS AND DISCUSSION OF THE VARIOUS GROUPS OF CONJUNCTIVITIS

1. BACTERIAL MEMBRANOUS CONJUNCTIVITIS

a. *Diphtheritic conjunctivitis*

Diphtheritic conjunctivitis may occur as: (1) An acute catarrhal conjunctivitis,

(2) a pseudomembranous conjunctivitis, and (3) a true membranous conjunctivitis. Sourdille³ first established the existence of the catarrhal form of diphtheritic conjunctivitis. This form responds readily to treatment with antitoxin. Sourdille^{2,3} and Stephenson⁶ have described a moderately acute form of diphtheritic conjunctivitis which is accompanied by pseudomembrane formation. This type is more severe than the catarrhal form. The symptoms usually subside following administration of diphtheria antitoxin. Most cases of diphtheritic conjunctivitis are accompanied by true membrane formation. Stephenson found membranes in 42 of 43 cases. Of these, 20 cases had a mild form of the disease, 19 were moderately severe, and 3 were severe. He stated that in most instances the patients showed pseudomembranes. The grave form of the disease is nearly always accompanied by true membrane formation, conjunctival necrosis, and sloughing. Corneal complications are frequent in this type of diphtheritic conjunctivitis.

CASE REPORT. *Acute diphtheritic membranous conjunctivitis.* Dr. H. C. I., aged 38 years, was admitted to the Institute of Ophthalmology, Presbyterian Hospital, April 4, 1941.

History. The patient awakened one morning with redness and watering of both eyes. He treated himself with zinc-sulfate drops for two days without improvement. He then shifted to mercurochrome (1 percent) for two days without effect. At this time local treatments with silver nitrate were commenced and within a few days he accidentally received a drop of 10-percent, instead of 1/2-percent, silver nitrate in each eye, which put him in bed for about a week. At the end of this time, conjunctival cultures showed only staphylococcus albus. He treated himself again for another week with mercurochrome but the membranes which had

developed failed to disappear.

Examination. There was a bilateral acute catarrhal conjunctivitis with membrane formation on the lower tarsal conjunctiva (fig. 1). The cornea was normal. Smears revealed numerous organisms having the morphology of *C. diphtheria*. Cultures showed a fair number of colonies possessing the characteristics of *C. diphtheria*. Subsequently, these organisms proved to be *C. diphtheria* by culture and guinea-pig inoculation.

Treatment. He was treated with diphtheria antitoxin intramuscularly and made an uneventful recovery.

Comment. This case presents a typical instance of chronic diphtheritic membranous conjunctivitis, persisting in spite of the ordinary forms of treatment but responding readily to diphtheria antitoxin.

Diagnosis. The diagnosis in acute diphtheritic conjunctivitis should be based upon the finding of typical organisms in smears and in cultures upon Loeffler's media. The virulence of these organisms must be confirmed by intraperitoneal inoculation of guinea pigs.

b. Acute streptococcic membranous conjunctivitis

Streptococcic membranous conjunctivitis may be accompanied by formation of either pseudomembranes or true membranes. The membranes which are encountered in moderate forms of the disease are usually pseudomembranous in type and are either transient or persistent. In these, the membrane appears during the second or third day of the disease, may be diffuse or localized, and principally affects the palpebral conjunctiva. The bulbar conjunctiva and cornea are rarely involved. The membranes persist for the duration of the acute infection.

Other cases⁹ are characterized by an acute fulminating conjunctivitis, edema of the lids, preauricular lymphadenopathy, diffuse palpebral and bulbar mem-

brane formation, early corneal involvement with perforation, and a profuse conjunctival discharge. A number of cases¹⁰⁻¹³ of chronic streptococcic conjunctivitis have been reported in which the infection was characterized by a brawny induration of the eyelids, extensive heavy membrane formation on the

Fig. 1 (Hogan). Diphtheritic membrane on tarsal conjunctiva.

palpebral and bulbar conjunctiva, secondary corneal involvement with perforation, and a strong tendency to form layers of connective tissue in the substantia propria of the conjunctiva. In most of the cases of this type the infection has persisted for 1½ to 8 years. The prognosis is poor as to vision but the conjunctival lesions seem to have been favorably influenced by penicillin, sulfonamides, and antistreptococcic serum.

CASE REPORT. *Acute streptococcic membranous conjunctivitis with corneal perforation.* V. C., a Negro girl, aged seven years, was first seen at the clinic of the Institute of Ophthalmology, Presbyterian Hospital in New York, on November 16, 1942.

History. The patient had an upper respiratory infection which commenced approximately on November 6, 1942. On November 11th, the right eye became inflamed and swollen and developed a yellowish purulent discharge. On the

following day, the left eye became involved in a similar manner. The swelling and discharge increased in amount each day until she was referred to the hospital for care.

Examination. There was marked edema of the lids of both eyes (fig. 2). They could be separated only with difficulty. The bulbar conjunctiva was markedly

Fig. 2 (Hogan). Bilateral streptococcic membranous conjunctivitis.

chemotic. There was a good deal of yellowish discharge. A yellow-white membrane covered the palpebral and bulbar conjunctiva and extended across the cornea. The membrane was heavy and could be lifted only with difficulty, leaving a raw bleeding surface.

Course. The patient was admitted to the Hospital. Smears and cultures on blood agar were taken, and sulfadiazine and sulfanilamide were given by mouth and by local instillation in solution. On the following day the patient was extremely toxic. The blood sulfanilamide level was 15 mg. percent, and the blood sulfadiazine level was 6 mg. percent. The cornea of the right eye ruptured during the afternoon of this day. The left cornea soon showed signs of advanced necrosis and perforated. Subsequent therapy gradually brought the conjunctival infection under control. By January 10, 1942, the membranes had disappeared and the

eyes showed beginning atrophy with extensively scarred granulating corneas.

Laboratory studies. The initial cultures on admission showed a pure culture of beta hemolytic streptococcus on both conjunctivas. Smears showed organisms which were morphologically similar to streptococci. In spite of continuous treatment, the smears and cultures from the membranes and corneas continued to be positive until January 8, 1942. The streptococci recovered from all of these cultures were reported to be in Group A, Type 25 (Lancefield). Subsequent cultures showed only occasional staphylococci and numerous diphtheroids.

Organisms from cultures on blood-agar plates were inoculated into the right cornea of a rabbit by the scratch method and into the left cornea by a penetrating needle. The right cornea developed a gray, 4-mm. nebula which cleared rather quickly. The left cornea developed a severe keratitis with necrosis superiorly and marked bulbar congestion. The infection subsequently subsided with formation of leukomas.

Comment. This case of acute streptococcic membranous conjunctivitis demonstrates the rapidity with which streptococci can invade the tissues, produce a severe inflammatory reaction, and result in corneal necrosis. The membrane formation in this case was in the nature of a true membrane. Streptococcic infections respond to penicillin and the sulfonamide compounds. Those patients treated early should rarely develop corneal complications. Swan and Allen¹⁴ have reported favorably on the use of sulfanilamide in streptococcic membranous conjunctivitis.

c. Acute membranous conjunctivitis due to other bacteria

The membranous conjunctivitis which occurs during the course of pneumococcal, Koch-Weeks, influenza bacillus, gonococcal, and intestinal bacillary infections is usually of the pseudomembranous

ous form. In some instances, the pseudomembrane is permanent and subsides only with healing of the conjunctivitis. In others, such as gonorrheal infections, the membrane is usually transient in character. Gifford¹⁵ stated that the pseudomembrane in pneumococcic infections was usually light and could easily be wiped off the upper tarsus. Morax¹⁶ described four cases of pneumococcic conjunctivitis in children which were unocular and accompanied by thin membranes. Clinically, the membranous conjunctivitis is identical in pneumococcic, influenza bacillus, and Koch-Weeks bacillus infections, and can be differentiated, as a rule, only by laboratory study. Knapp¹⁷ reported a six weeks' old infant with inflamed eyes and fibrinous membranes on the upper lids. The child developed right corneal involvement 12 days after onset of the disease. He was able to culture the influenza bacillus on blood-agar plates, from material removed from the conjunctiva. Yakovleva¹⁸ has reported a family epidemic of acute catarrhal conjunctivitis due to *B. faecalis alcaligenes* and *B. dysentery liquefaciens*. Five cases of the disease developed and of these a 2½-year-old girl had a thick membrane which was difficult to remove. She also had thickened, heavy lids and a profuse purulent discharge.

Comment. The diagnosis in these acute forms of conjunctivitis with membrane formation is usually made by examining stained smears of the conjunctival exudates and by the culturing of the causative organisms on suitable media.

Treatment. It is best to direct treatment toward eliminating the causative organism and providing palliation of the patient's symptoms. The pneumococcus and gonococcus respond to sulfonamides and penicillin administered locally and systemically. Koch-Weeks and influenza bacillus infections usually respond to mild antiseptics and are self-limiting infec-

tions. There is a possibility that conjunctivitis due to intestinal bacteria may be relieved by local streptomycin therapy.

d. Chronic tuberculous membranous conjunctivitis

Most cases of conjunctival tuberculosis are characterized by either ulcerative or nodular lesions. Gourfein¹⁹ reported the case of a six-year-old girl with swelling, redness, and discharge from the right eye. On examination, the upper tarsal conjunctiva was covered with a gray false membrane. It detached with difficulty and resulted in bleeding but there was no underlying ulcer. There was a right preauricular, submaxillary, and parotid lymphadenopathy. Chest examination was negative. The lesion was completely healed in 21 days without complication. Cultures showed only the staphylococcus albus. Guinea pigs were inoculated with bits of the false membrane and died four months later of generalized tuberculosis. The purulent exudate from several glands was also injected subcutaneously into guinea pigs and they died three months later of generalized tuberculosis. Conjunctival secretion was injected into the anterior chamber of guinea pigs with formation of tubercles on the iris and subsequent death of the animals from generalized tuberculosis.

Comment. The course of the disease in the above case is somewhat atypical, and the author does not say whether or not he observed tubercle bacilli in smears from the conjunctiva. However, the animal inoculations in this case are rather convincing, and it must be presumed that the case is actually one of chronic tuberculous membranous conjunctivitis.

2. MEMBRANOUS CONJUNCTIVITIS DUE TO VIRUSES

a. Inclusion blennorrhoea

During the acute phase of inclusion blennorrhoea a pseudomembrane may form on the palpebral conjunctiva both inferi-

Fig. 3 (Hogan). Pseudomembrane in epidemic keratoconjunctivitis.

only and superiorly. This membrane is temporary and usually disappears within 10 days to 2 weeks. The membrane, at times, may be quite transient. Thygeson²⁰ has pointed out that no sequelae are noted except that marked pseudomembranous infections may be followed by fine conjunctival scars.

b. Epidemic keratoconjunctivitis

Membrane formation in epidemic keratoconjunctivitis was first reported in 1942 by Hogan and Crawford.²¹ Of their 125 reported cases, 17 patients developed membranes on the conjunctiva of the eyelids.

CASE REPORTS. These 17 patients were seen in the fall of 1941. They all had typical cases of epidemic keratoconjunctivitis and exhibited conjunctival membranes. The membrane made its appear-

Fig. 5 (Hogan). Membrane in epidemic keratoconjunctivitis.

ance in each of these patients between the 4th and 8th days after onset of the disease. At first it was thin and milky in appearance and was usually located on the tarsal conjunctiva near the fornix. It could be wiped off easily. In three cases, the membrane persisted in this form for several days and then disappeared (fig. 3). In the other 14 cases, the membrane continued to form and extended medially onto the caruncle and semilunar fold and toward the margin of the lids. In two instances, a thin pseudomembrane occurred on the bulbar conjunctiva inferiorly (fig. 4). As the membrane developed it became more dense and white and in four cases was difficult to remove (figs. 5 and 6). Moderate bleeding occurred after removal. The membrane in these more severe cases usually lasted from 6 to 8

Fig. 4 (Hogan). Thin membrane in epidemic keratoconjunctivitis.

Fig. 6 (Hogan). Membrane in epidemic keratoconjunctivitis.

days. After subsidence of the infection, no scars were noted on the conjunctiva.

Sporadic cases of epidemic keratoconjunctivitis have been seen since 1942, but no instances of membrane formation have occurred until this year. The membrane, in the more recent cases, is thin in appearance and more transient in duration. In addition, we have also noted atypical forms of the disease. Recently a physician was seen who developed a bilateral acute catarrhal conjunctivitis, more severe in the right eye. There was a pseudomembrane on the tarsal conjunctiva of the right eye but none on the left, and there was no preauricular lymphadenopathy. There were fine scattered epithelial corneal infiltrates in both eyes. Laboratory studies showed organisms resembling *C. diphtheria* in smears, but repeated cultures showed only diphtheroids, non-pathogenic to guinea pigs. The patient was treated with diphtheria antitoxin, 40,000 units being given on two occasions. He showed steady improvement and the conjunctivitis was cured within 10 days. He had been treated with penicillin before coming for advice, so that if his infection was originally diphtheritic the organisms were probably gone by the time the above studies were made. At present, this patient shows corneal opacities which are exactly similar to those of epidemic keratoconjunctivitis. The wife of this patient also developed a conjunctivitis but without membrane formation. Her infection was accompanied by epithelial lesions which resembled those of a herpetic keratitis. Laboratory studies on this patient were negative. Five patients of the above physician also developed an acute conjunctivitis during the course of his infection. In these patients a keratitis developed which had the features of a dendritic keratitis.

Comment. The clinical features of epidemic keratoconjunctivitis, together with

the laboratory findings, especially the observation of a predominantly lymphocytic exudate in scrapings, serve to distinguish this disease from most others with membranous conjunctivitis. Treatment in these cases, so far, is of little value except that palliative measures may render the patient more comfortable. Convalescent serum may eventually prove to be of value, especially if given in the early stages of the disease.

c. Herpes febrilis

Clausen,^{22, 23} Aust,²⁴ and Batagnani²⁵ have shown that a catarrhal form of conjunctivitis may occur in herpes febrilis, especially if the patient has lesions on the lid margins. Aust, Loewenstein,²⁶ Granström,²⁷ and Larsson and Granström,²⁸ have reported cases of acute conjunctivitis associated with marginal lid lesions, membrane formation, severe pain, regional lymphadenopathy, and constitutional symptoms. A number of these patients subsequently developed dendritic keratitis or exhibited superficial epithelial corneal infiltrates. Rabbit corneal inoculations with scrapings from these cases were accompanied by development of a keratitis, conjunctivitis, iritis, and, at times, cerebral symptoms. Loewenstein thinks that the infections in these cases originate on the lid margins and result in pseudomembranous conjunctivitis with corneal lesions. Granström and Larsson think the herpes virus must be suspected as a cause of violent cases of unilateral conjunctivitis in which a bacterial factor cannot be proved. They conclude that the development of keratitis, enlarged lymph nodes, membrane formation, and positive rabbit inoculations confirm the diagnosis.

d. Vaccinia

Many reports have been made concerning the development of conjunctivitis and corneal ulcers during the course of smallpox. A number of articles state that the streptococcus is frequently cultured from

the conjunctiva in cases showing the eye complications of smallpox. It is probable that the conjunctival pustules become secondarily infected in many instances, with development of severe ulceration and membrane formation. Almost 100 cases of accidental vaccination of the conjunctiva have been reported. Most of the reported cases have developed the conjunctival lesion as a result of contact with the vaccinia vesicle on other persons (case 2, below).

CASE REPORT. (1) In 1946 a patient was seen who developed an accidental vaccinia of the eyelids accompanied by a membranous conjunctivitis. The patient, a woman, aged 35 years, had been vaccinated on the right arm eight days prior to coming for treatment. She had noted swelling of her right eyelids for three days, with redness and moderate discharge from the conjunctiva.

Examination. There was marked edema and redness of the lids. The conjunctiva was edematous and congested. There was a thin, pale, white, pseudomembrane on the lower tarsal conjunctiva and fornix. The cornea was normal. There was a small nodule topped by several vesicles on the upper lid temporally. A vaccinia pustule was present on the right arm.

Course. The conjunctivitis subsided slowly and the pseudomembrane disappeared from the conjunctiva in five days, without scarring.

CASE REPORT (2). I am indebted to Dr. Margaret Henry for permission to present the findings in this patient. A Negro girl, aged six years, was admitted to the Children's Hospital on April 17, 1946, with the history that three days previously the left lower lid had become swollen. Within 24 hours she could not open her eye. Skin lesions soon appeared on the eyelids and bridge of her nose. Her physician administered 20,000 units of diphtheria antitoxin the following day

and referred the patient to the Hospital.

Examination. The appearance of the left eye was striking. There was marked periorbital edema and cellulitis, extending above the eyebrow, across the nose, and down onto the cheek. There was a watery discharge from the eye, and the lids were covered with a dry purulent exudate. There were several small vesicles on the eyelid and one umbilicated vesicle on the bridge of the nose. There were also a number of vesicles on the lid edges. On retracting the lids, there was a thin pseudomembrane on the lower tarsal conjunctiva near the lid margin and on the upper tarsus centrally.

Course and Treatment. The patient was given another 20,000 units of diphtheria antitoxin intramuscularly. Four days later she was afebrile, and the conjunctival and lid lesions were nearly well. The lesion on the bridge of the nose looked like a primary vaccinia. Five days later the patient developed a small, pinhead-sized ulcer at the 6-o'clock position on the cornea which healed rapidly under treatment with tincture of iodine. She was discharged on April 28th.

Laboratory findings. Repeated cultures and smears of the conjunctiva showed no pathogenic organisms. Throat cultures showed no diphtheria bacilli. The Kahn test was negative.

Comment. There is some debate as to the etiology of this condition, as the child had no history of vaccination. However, she had been playing with cousins who had active vaccinia lesions and she may have contracted the virus from them. She was vaccinated twice while in the Hospital and showed an immune reaction. The clinical appearance of the lesion on the bridge of the nose was rather typical, so that a diagnosis of vaccinia membranous conjunctivitis was made in this case. The experiments of Folk and Taube²⁹ provide ample evidence that vaccinia virus, intro-

duced on the conjunctiva, is well able to produce a membranous conjunctivitis without a previous abrasion. In spite of the severity of the clinical picture in these cases the prognosis is surprisingly good, and most reports indicate that the lesions heal without visual loss in about 90 percent of the cases.

3. MEMBRANOUS CONJUNCTIVITIS DUE TO HIGHER PLANT PARASITES

At times, a conjunctivitis may develop in patients suffering from general debilitating diseases. Cases have been reported in which smears showed fungi or other parasites. Usually other organisms have been encountered in addition to the fungi, and the decision as to the nature of the causative agent is difficult. Most fungus infections of the conjunctiva are granulomatous in form, and rarely become diffuse with membrane formation. Several case reports have been made describing membranes on the conjunctiva due to *Oidium albicans* and the streptothrix.

a. *Thrush*

Norton³⁰ reported the case of a five-year-old boy who exhibited symmetrically placed white growths nasally and temporally outside the limbus in the palpebral fissures. The outer lesions were triangular in shape and the inner ones were smaller and quadrilateral. This case was followed for a month, and the lesions recurred quickly after removal. The conjunctiva beneath the lesions was wrinkled, yellowish, and slightly chemotic. Otherwise, the conjunctiva was normal, and the boy had no symptoms. Smears and cultures showed monilia candida with mycelium and spores. A sister of this boy was said to have the same condition.

Pichler³¹ reported two cases. The first was of a four months' old child having a severe pseudomembranous conjunctivitis and an aphthous stomatitis. The child's nurse was similarly affected orally.

Oidium albicans was found on the membranes. The second case, that of a three-year-old girl with several exanthematous diseases, showed general emaciation and acute conjunctivitis. There was a white dry membrane on the tarsal and bulbar conjunctivas and the corneas. Similar lesions occurred in the mouth and nose. The conjunctival and corneal lesions resulted in scarring and opacification. *Oidium albicans* was found in smears from the conjunctival and oral lesions, but cultures were unsuccessful.

b. *Streptothrix*

May³² reported a patient with conjunctivitis accompanied by a firmly adherent thin, yellow-white membrane. The bulbar conjunctiva was red and thickened. There was an ulcer below the limbus measuring a quarter of an inch in diameter. It was covered by a thin membrane. Smears and cultures were negative, but tissue sections showed the streptothrix.

4. MEMBRANOUS CONJUNCTIVITIS CAUSED BY TOXIC AGENTS

a. *Erythema multiforme*

The first case of erythema multiforme associated with conjunctival lesions was reported by Fuchs,³³ in 1876. Since that time, a large number of cases have been reported.³⁴⁻³⁸

In general, two conjunctival forms of the disease are seen: (1) A mild simple catarrhal conjunctivitis, and (2) a severe membranous conjunctivitis. The onset in most cases is similar to an acute infectious disease with chills, fever, headache, and malaise. The skin lesions are widespread and polymorphous in character. Conjunctivitis, rhinitis, stomatitis, and pharyngitis are frequently seen.

The ocular lesions usually consist of an intense pseudomembranous inflammation of the conjunctiva and corneal epithelium. The prognosis, from an eye standpoint, is frequently unfavorable. Raffin³⁹ has

stated that the lesions are primarily inflammatory, soon become covered with fibrin, and appear as pseudomembranes. Ulceration is not uncommon and symblepharon may occur. Corneal involvement occurs all too frequently. It commences with edema of the epithelium and stroma. Membrane formation follows and leads to ulceration and perforation. Healing always occurs, with a certain amount of atrophy and scarring.

Erythema multiforme is usually due to sensitivity to drugs or sera. Spontaneous cases may occur in young people and in them the causative agent is rarely determined. Most people are agreed that the disease is toxic in origin.

Two cases have been seen during the past few years which have presented the features of erythema multiforme accompanied by mucous membrane involvement. I am indebted to Dr. David O. Harrington and Dr. Margaret Henry for permission to present them.

CASE REPORT (1). A. K., a white man, aged 35 years, was admitted to the United States Veterans Hospital in San Francisco on September 29, 1946, for treatment of cerebral concussion and a compound fracture of the skull. During the course of his treatment he received 30,000 units of penicillin intramuscularly every four hours and 1 gm. of sulfadiazine by mouth every four hours. This was continued for 18 days, at which time he developed a severe generalized dermatitis, characteristic of erythema multiforme. The conjunctival and oral mucous membranes were markedly affected and he had a temperature of 104°F. In spite of the high degree of fever, his white blood count remained at around 5,000 cells per cubic ml., with a normal differential count.

Eye examination. The lids and conjunctivas were markedly chemotic, with a thick tenacious mucoid discharge. A thin pseudomembrane covered the lid and

bulbar conjunctivas. Treatment was symptomatic and improvement was slow. Ulcers formed beneath the pseudomembranes, and there was a marked tendency to form a symblepharon. Attempts to separate the membranes left raw bleeding areas. At first there was no corneal involvement, but as the disease progressed, a gray haze was seen superficially. At the end of 15 days, the cornea was clear and membrane formation ceased. Subsequently it was noted that there were two quite firm adherent symblepharons in the upper and lower fornices of both eyes. There was no limitation of motion of the globes. Visual acuity was normal.

CASE REPORT (2). Mrs. K. A., aged 28 years, was first seen at Children's Hospital on October 10, 1944, complaining of a skin eruption with pruritus, headache, sore throat, and swollen eyes and lips for 48 hours.

History. The patient had been perfectly well until 48 hours before admission, when she noted the signs of an upper respiratory infection, including headache, malaise, a nasal discharge, backache, pains in her legs, and sore throat. Twenty-four hours later a conjunctivitis developed in both eyes, and later the same day puffiness of the lips. She had extreme difficulty in swallowing. Six to eight hours prior to onset of the conjunctivitis she had taken an aspirin preparation containing phenolphthalein. Twelve hours before admission her physician commenced sulfathiazole (2 gm.), followed by 1 gm. every four hours. On the morning of admission the patient developed a scattered rash on the skin. Her family and past medical histories gave no indication of a cause of the present illness.

Examination. The patient was acutely ill. There was a generalized eruption of the face, trunk, and extremities, including the palms of her hands and soles of her feet. The mucous membranes of the eyes were edematous and injected; the mouth

showed a peculiar purplish-yellow discoloration.

Eye examination. The eyes were swollen shut and there was an acute bilateral conjunctivitis with severe photophobia and a serous discharge. The corneas and intraocular structures appeared normal.

Course. The skin and mucous membrane lesions remained very much the same until October 18, 1944 (one week later), at which time the patient complained of inability to see from the left eye. On examination there appeared a rather extensive pale-yellow gelatinous membrane on the conjunctiva of the right eye. A similar membrane on the left eye completely covered the bulbar conjunctiva and the cornea. The membrane over the cornea was lifted up by a serous exudate and air, forming a very extensive bulla. Cultures were taken at this time, and it was seen that the membrane over the left cornea was easily removed with the applicator. The underlying cornea appeared normal. Two days later the corneal membrane was gone in the left eye, but that on the palpebral conjunctiva remained. On October 25, 1944, the conjunctivitis was practically well and there was no secretion. A few white linear scars could be seen on the upper palpebral conjunctiva. The corneas appeared normal. By October 30, 1944, the skin lesions had practically disappeared. The condition of the lips and mouth was still bad, although healing. She was discharged to the care of her family physician at this time.

Comment. These two cases illustrate the development of erythema multiforme accompanied by mucous-membrane lesions as a result of the toxicity of drugs. The course of the disease in both cases was unusually favorable, inasmuch as the corneas were not damaged. The membrane which forms in erythema multiforme is more of the nature of a true membrane, as necrosis of the conjunctiva

occurs and scarring may result. Treatment in cases of this type must be directed along general lines to eliminate the toxic agent. Local therapy should be aimed at preventing corneal complications and symblepharon.

b. Pemphigus

Pemphigus is a toxic disease which may affect the eyes in both the acute and chronic forms. In those cases which present a vesicular eruption on the conjunctiva, the vesicles not infrequently rupture and the fibrinous fluid coagulates to form thin localized membranes. Diffuse membrane formation is not characteristic of pemphigus, but local pseudomembranes may form in the areas of ruptured vesicular lesions.

5. ALLERGIC MEMBRANOUS CONJUNCTIVITIS

a. Vernal catarrh

Thin transient membranes may form on the conjunctiva of the tarsus at any time during the acute phase of vernal catarrh. These transient membranes seem to depend upon the coagulation of a fine film of fibrin on the inner surface of the epithelium. Herbert⁴⁰ mentions that, if the lids are held everted for a short while, a fine membrane may be produced, and that if an examination is made at this time, eosinophils can be found. Lehrfeld^{41, 42} distinguishes the milky film which has been described in vernal catarrh and which is due to the subepithelial hyaline degeneration, from the thick, ropy, lardaceous film which occurs on the mucous membrane in this disease. He states that this tenacious fibrinous membrane is somewhat elastic and can be wiped off without bleeding.

6. MEMBRANOUS CONJUNCTIVITIS DUE TO CHEMICALS

That a membranous conjunctivitis may be produced by chemicals has been shown by numerous observers.^{2, 43} Most of the

original work on the pathology of membrane formation was done following chemical production of the membranes. Jequirity, lime, ammonia, and silver nitrate are the drugs most frequently mentioned as producing membranes. Arsenic administered parenterally may produce a toxic reaction with exfoliative dermatitis and mucous-membrane lesions. Hegner⁴⁴ mentions a patient who received neoarsphenamine and developed an exfoliative dermatitis. A pseudomembranous conjunctivitis occurred, followed by corneal necrosis and panophthalmitis.

The development of membranes on the conjunctiva, following chemical injury, depends upon the ability of the drug to penetrate the epithelium, upon its concentration, and duration of action.

7. MEMBRANOUS CONJUNCTIVITIS DUE TO UNKNOWN OR UNCERTAIN CAUSES

A fairly large number of cases of chronic membranous conjunctivitis have been reported under a variety of titles. In a number of these,⁴⁵⁻⁴⁹ bacteriologic studies revealed organisms, such as staphylococci, streptococci, and so forth. It is probable that most of these chronic membranous conjunctivitis cases are streptococcal in origin.^{13, 50} Among other cases which have been described, the membranes formed over ulcerated areas of the conjunctiva and were followed by granulomatous overgrowths. Later organization of these granulomas led to the formation of dense masses of connective tissue resembling hyaline.

Future cases of this type will probably be classified among the above described groups of bacterial conjunctivitis.

IV. STUDIES OF THE PATHOGENICITY OF DIPHTHEROIDS

In connection with diphtheritic membranous conjunctivitis, an attempt was made to determine if pathogenicity could

be induced in any of the diphtheroids recovered from the conjunctiva. The diphtheroid organisms are generally considered to be saprophytic; and the organisms on the conjunctiva have never been thought to become pathogenic.⁵¹ Numerous experiments designed to determine this pathogenicity have failed. On occasions pathogenic diphtheroids have been recovered in infections occurring in other portions of the body.⁵²⁻⁵⁴

There is evidence that some strains of diphtheroids, such as *C. ovis*⁵⁵ and *C. ulcerans*^{56, 57} produce toxins and that some of these organisms are capable of causing human infections. Reference should be made to the case of chronic membranous conjunctivitis reported by Dunphy⁵⁸ in which organisms of the diphtheroid group were isolated.

METHODS

Corynebacteria were recovered from the conjunctivas of 100 patients with a variety of conjunctival affections. These strains were obtained by implanting smears from the conjunctivas onto rabbit blood-agar plates. Colonies of diphtheroids were taken from the blood-agar plates and implanted in beef broth. After 24-hour incubation at 37°C., a loopful of the broth was spread on blood-agar plates. By further transplantation, pure cultures were then obtained in beef broth. The resulting 48-hour growth of the pure strain in this beef broth was used for morphologic studies, animal inoculations, and fermentation reactions.

The following animal studies were made:

a. Forty-eight-hour broth cultures of each strain were inoculated into the conjunctivas of mice, rabbits, and guinea pigs, one drop at a time at 10-minute intervals, for four hours.

b. One-tenth cc. of a 48-hour broth culture of each organism was injected

beneath the conjunctivas of guinea pigs, rabbits, and mice.

c. One-tenth cc. of a 48-hour broth culture of each organism was injected into the anterior chambers of rabbits and guinea pigs.

d. An equal portion of a 48-hour broth culture of each strain was mixed with an equal amount of *mucin*. Drops of this mixture were instilled into the conjunctival sacs of rabbits and of guinea pigs at 10-minute intervals for four hours.

e. Utilizing the same mixture as in (d) above, 0.1 cc. was injected into the anterior chamber and into the vitreous of mice, rabbits, and guinea pigs.

g. Diphtheria toxin was obtained diluted with saline so that it contained 450 m.l.d. per cc. This toxin was standardized so that upon instillation of one drop into a rabbit's conjunctival sac every 5 to 10 minutes for 2 to 2½ hours, a purulent conjunctivitis could be produced, which subsided within 2 to 4 days. This toxin was instilled into the conjunctival sac of rabbits every 10 minutes for two hours, followed each time by the instillation of a drop of a 48-hour broth culture of diphtheroid organisms. This procedure was carried out with the organisms derived from 10 different patients.

h. The toxin was instilled into the

Fig. 8 (Hogan). Large granular colonies of diphtheroids (Magnification $\times 140$).

conjunctival sacs of rabbits and monkeys at 10-minute intervals for six doses. The conjunctival membrane was then lightly scrubbed with an applicator which had been dipped into a broth suspension of diphtheroids derived from five patients.

RESULTS

a. *Colony morphology.* The colony morphology was studied on 24-hour blood-agar cultures. Two main varieties of colonies were encountered in this study, the most frequent type being small, round, flat, and very slightly granular (fig. 7). The other type was larger, more elevated, round, and coarsely granular (fig. 8). This latter type might correspond with the previous descriptions of *C. xerosis* which was described as having a peculiar dryness or scaliness of growth on media.

b. *Cellular morphology.* Three main types of organisms were encountered in this series of cultures: (1) Slender, curved rods of varying length and an irregular staining protoplasm (fig. 9). (2) Small, thick rods, which stained either solidly or were barred and wedged (fig. 10). (3) Coccoid forms (figs. 11 and 12).

Fig. 7 (Hogan). Smaller granular diphtheroid colonies (Magnification $\times 10$).

Fig. 9 (Hogan). Slender curved diphtheroids (Magnification $\times 1,200$).

The above descriptions apply to 24-hour cultures only. It is well known that after 24 hours, clubbing, irregular staining, elongation, and segmentation are more frequently encountered. No organisms were encountered which fulfilled the essential character of *C. xerosis*; and

Fig. 10 (Hogan). Short, thick, rodlike diphtheroids (Magnification $\times 1,200$).

Fig. 11 (Hogan). Coccoid forms of diphtheroids (Magnification $\times 1,200$).

it is doubtful if *C. xerosis* is sufficiently characterized to deserve special mention in reports.

C. Hofmanni fits the description of the second organism (fig. 10), and the cultural characteristics bear out the presence of this organism on the conjunctiva:

c. Fermentation reactions. The tabulated results of fermentation reactions are recorded in Table 1.

Fig. 12 (Hogan). Coccoid diphtheroids (Magnification $\times 1,200$).

d. Animal experiments. In none of these experiments with the cultures of diphtheroids, alone or in conjunction with mucin, or with diphtheria toxin, was it possible to produce any ocular infections.

COMMENTS

It is concluded from these experiments that diphtheroid organisms encountered on the conjunctiva during the course of infectious conditions probably play no part in the production of conjunctivitis and rarely, if ever, contribute to the pro-

duction of intraocular infections. This work confirms previous experiments done on conjunctival diphtheroid organisms. The consideration arose, however, that these diphtheroid organisms might be rendered pathogenic if they could be protected by a substance such as mucin. Similarly, it was reasoned that the virulence might be developed if the resistance of the conjunctiva could be lowered by the use of diphtheria toxin alone or in conjunction with trauma. It was not found to be possible to alter the saprophytic nature of the organisms encountered. It was felt that occasional pathogenic diphtheroids might be encountered which might cause conjunctival disease, such as those described by Gilbert and Stewart and Reudiger.

None of the organisms encountered showed the characteristics of *C. ulcerans*

or *C. pyogenes*. Cultures of *C. ulcerans* were obtained through the courtesy of Dr. Ruth Gilbert of the New York State Department of Health. These organisms invariably produced a rapid and destructive panophthalmitis when injected into the anterior chamber. It was noted that the effects of these injections could be minimized in guinea pigs and rabbits by the administration of diphtheria antitoxin. Unfortunately continued pursuance of this subject was interrupted by the war. Further studies will be made on the

effect of *C. ulcerans* on the eye and its relationship to other ocular diphtheroids.

CONCLUSIONS

1. A classification of cases of conjunctivitis which develop membranes is presented.

2. The pathogenesis of membrane formation which accompanies various types of conjunctivitis is discussed.

3. The nature of the membrane formation among the various groups is discussed and case reports are given of typical examples in some of the groups.

4. Diphtheroids from 100 cases of external ocular disease were recovered in pure culture and studied for pathogenicity. No pathogenic organisms were encountered.

5. Attempts to enhance the pathogenicity of diphtheroids by utilizing the pro-

tective effect of mucin were unsuccessful.

6. Attempts to produce diphtheroid infections of the conjunctiva by lowering the resistance of the conjunctiva with diphtheria toxin and trauma were unsuccessful.

7. *C. ulcerans*, an organism recovered from the throat by Gilbert and Stewart produced a panophthalmitis on intraocular injection, but the effects could be

minimized by previously administered diphtheria antitoxin.

Appreciation is expressed to Dr. Philips Thygeson and Mrs. Clement McCulloch for valuable suggestions and assistance in carrying out the work of this paper.

DISCUSSION

DR. F. H. VERHOEFF (Boston, Massachusetts): I notice that every type of membrane that I have ever seen and some that I haven't are mentioned in the abstract, but a membrane that sometimes occurs in a condition we used to call scrofula doesn't seem to be included. One seldom hears that term used any more. We frequently used "scrofulous diathesis," in cases of children with enlarged glands. Probably tuberculous adenitis was always at the bottom of this condition. Some of those patients, instead of getting phlyctenular conjunctivitis, would have an inflammatory membrane on the palpebral conjunctiva. I wonder whether you are acquainted with such membranes?

It seems to me, several years ago, there was a paper given before this Society on a membranous conjunctivitis of infants. Did you see that?

DR. M. J. HOGAN (San Francisco): Yes, I did.

DR. VERHOEFF: Have you referred to that?

DR. HOGAN: Not in this paper.

DR. VERHOEFF: It was a very excellent paper. The conjunctivitis was of quite a severe type, as I recall it. It was often associated with the formation of a poly-poid growth, wasn't it?

DR. HOGAN: Yes, sir.

DR. VERHOEFF: I noticed reference to experiments on the inoculation of pseudo-diphtheritic membranes in the conjunctiva of animals. If you made such experiments with diphtheria bacilli, I am glad I wasn't around when you did so.

DR. HOGAN: We used diphtheria toxin only.

DR. VERHOEFF: You don't mention it here.

DR. HOGAN: I mentioned it in this abstract.

DR. VERHOEFF: I see. I couldn't hear you well enough to know whether you mentioned it.

DR. HOGAN: Morax, Elmassian, and Sourdille were able to produce membranous conjunctivitis with diphtheria toxin alone or by inoculation of the cultures of diphtheria organisms.

DR. VERHOEFF: I should not have feared being around when you used the toxin, but wasn't it a rather dangerous procedure in the laboratory to have diphtheria bacilli in the conjunctiva?

DR. HOGAN: We did not use the bacilli.

DR. VERHOEFF: I see. Well, perhaps you're lucky.

DR. HOGAN: I did not mention tuberculous membranes of the conjunctiva here, but it is discussed in the paper.

DR. VERHOEFF: And you didn't mention that type of membrane I was speaking about, did you?

DR. HOGAN: No, I eliminated the term scrofulous because I think probably some of those cases would be placed in other groups, either streptococcic or some other form of bacterial or toxic membranous conjunctivitis.

DR. VERHOEFF: I imagine you could put it under those, but we used to call it scrofulous.

DR. PARKER HEATH (Boston, Massachusetts): You mentioned the word "trau-

matic," and I wish you would elaborate on trauma, with or without hemoglobin, forming a membrane.

DR. HOGAN: Most of the cases of membranous conjunctivitis which follow trauma are those in which a child or adult receives a laceration of the conjunctiva, with or without bleeding, in which the membrane forms. A localized membrane may form in the area of the laceration, which, as a transient membrane, of course, is dependent on the healing of the wound.

Usually the wounds are clean, and the formation of a membrane depends on the formation of a fibrin clot within the wound itself.

DR. HEATH: There is a membrane, if I may speak once more, associated with hemoglobin which forms a second membrane, a real membrane, on top, which persists. It is not transient. Have you noted that?

DR. HOGAN, (closing): No, I have not noticed that.

STUDIES ON THE PHYSIOLOGY OF THE EYE USING TRACER SUBSTANCES*

I. THE STEADY-STATE RATIO OF SODIUM BETWEEN THE PLASMA AND AQUEOUS HUMOR IN THE GUINEA PIG

ROY O. SCHOLZ, M.D.[†]
Baltimore, Maryland

DEAN B. COWIE, PH.D.[‡]
Washington, D.C.

AND

WALTER S. WILDE, PH.D.[§]
New Orleans, Louisiana

These studies were undertaken as part of a plan to investigate the permeability of mammalian membranes. The eye is a specially suitable organ for such studies because its fluids can be tapped without appreciably disturbing its normal state. As has been pointed out frequently^{1, 2} the use of radioactive isotopes offers a unique method for permeability

studies. In this first report we shall discuss the steady-state ratio of sodium between the plasma and aqueous humor and in the second report³ we shall discuss the turnover rate of sodium between these two fluids and the methods of analyzing such data.

The steady-state ratio between the plasma and aqueous humor of sodium has been studied by classical chemical methods in several species but not in the guinea pig (table 1), and it is noted that there is little agreement concerning the ratio even in the same species. It is important that the ratio of sodium between the plasma and aqueous humor be accurately determined in order to understand the mechanism of formation of the aqueous humor. If there is an excess of sodium in the aqueous humor, this may be

* Presented at the 16th scientific meeting of the Association for Research in Ophthalmology, Inc., Atlantic City, June 1947.

† Wilmer Ophthalmological Institute of Johns Hopkins University and Hospital.

§ Carnegie Institution of Washington, Department of Embryology, Baltimore. (Present address: Physiology Department, Tulane University, New Orleans 15, Louisiana.)

explained either by a secretory mechanism or by the loss of water from the aqueous through the cornea. In measurements in guinea pigs of the steady-state ratio using radioactive sodium (Na^{24}) as a convenient ultramicro method, we found the concentration ratio of plasma sodium to aqueous sodium to be lower than that reported for other species.

METHODS

Radioactive sodium (Na^{24}) was prepared in the 60-inch cyclotron of the De-

TABLE 1

partment of Terrestrial Magnetism, Carnegie Institution of Washington. Metallic sodium, after deuteron bombardment, was dissolved as sodium alcoholate in 95-percent ethyl alcohol. Sodium chloride was precipitated by addition of concentrated hydrochloric acid. The precipitated sodium chloride was dissolved in water, filtered, dried on a hot plate to remove excess HCl, and the NaCl finally dissolved in a volume of water suitable for injection.

Adult guinea pigs of mixed breeds, weighing between 500 and 1,000 gm., were used. The animals were fed rabbit pellets and fresh greens. Friedenwald and his co-workers have shown¹² that vitamin-C deficient guinea pigs have a lowered rate of formation of intraocular fluid. As a precaution against vitamin-C deficiency in our guinea pigs, each animal received 50 mg. of ascorbic acid 24 hours prior to the introduction of the tracer substance.

Three tenths of a cubic centimeter of an NaCl solution, containing about 1.336 mM/cc. was injected into the peritoneal cavity. After 24 hours, the aqueous was removed with a glass capillary pipette. Immediately thereafter a sample of blood was taken by cardiac puncture. Only brief

			X = 0.920 = 0.033

* Pe = equilibrium plasma.

† Ae = equilibrium aqueous.

ether anesthesia was necessary to carry out these procedures.

The weight and radioactivity determination of plasma and aqueous were made in shallow weighing bottles of uniform dimensions. The aqueous was delivered from the pipette to a weighing bottle which was immediately covered. The blood was oxalated and centrifuged

and then 0.1 cc. of plasma was delivered to a weighing bottle. After determination of the wet weight of the aqueous and plasma samples, they were spread uniformly over the bottom of the weighing bottles by the addition of a measured amount of water. The samples were then dried and the dry weight determined.

Measurements of the radioactivity of the samples were made with a pressure ionization chamber connected to a string electrometer.¹³

RESULTS

The beta particles per second per gram of aqueous water or plasma water were calculated and the concentration of tagged sodium was expressed in millimoles of sodium per kilogram of water. The average equilibrium ratio of plasma to aqueous was found to be $0.920 \pm \sigma = 0.03$ (table 1).

DISCUSSION

The Donnan ratio of plasma to body fluid for sodium has been reported to have a theoretical value of 1.04 in dogs (Van Slyke) when all of the sodium in the plasma is ionized. Green and Powers¹⁴ and Ingraham, Lombard, and Visscher¹⁵ have shown by *in vivo* dialysis and by *in*

vitro ultrafiltrates of dogs' plasma that proteins depress the activity of sodium in the plasma by binding it in a nondiffusible form. This removes approximately 8 to 11 percent of the sodium from consideration in the Donnan equilibrium and raises the theoretical value to around 1.12.

If we may transfer these values from the dog to the guinea pig, a considerable difference is evident between the theoretical and experimental ratio. The difference between the theoretical ratio of 1.12 in dogs and our reported ratio of 0.920 in guinea pigs may be due to several factors: (1) A species difference, (2) the passage of water from the aqueous through the cornea to the tears and the subsequent concentration of sodium in the aqueous, and (3) the secretion of sodium into the aqueous by the ciliary body or iris.

SUMMARY

1. Radioactive sodium was used as a tracer to study the distribution of sodium between the plasma and aqueous and between aqueous and lens in the guinea pig.

2. The steady-state ratio; sodium plasma/sodium aqueous was found to be 0.920.

One method of characterizing a membrane is to inquire whether the steady-state concentration gradient maintained across it is of such magnitude as would require the expenditure of energy locally in the membrane itself. This is essentially the method of our first paper in this series⁷ in which we measured the steady-state ratio of sodium tagged with radiosodium (Na^{24}) between the plasma and aqueous humor of the eye of the guinea pig and inferred from this ratio that a considerable excess of free sodium is present in the aqueous humor of guinea pigs such that its maintenance might indeed require an expenditure of energy locally at the blood-aqueous barrier.

Another method is to measure the rate at which different solutes cross the membrane. One can then describe the permeability of the membrane with respect to the

physicochemical properties of various ionic and molecular species. One may also study the effect upon the transfer rate of applying a number of different experimental conditions or chemical agents. For these, it is best to study the transfer of a naturally occurring constituent that is intrinsic to the medium bathing the membrane. The tracer technique is ideally suited to this in that one may work with a mere trace of material which does not upset normal ionic or molecular ratios.

We have attempted in the experiments to be reported here to gain a measure of the permeability of the plasma-aqueous barrier to sodium by determining the rate of transfer of sodium into the aqueous humor of the guinea pig using radiosodium (Na^{24}). Particular effort has been made in this initial work to analyze the difficulties involved in calculating rates from tracer data. The analysis is developed by describing two current approaches to the problem, the direct or linear,^{2,8} and the indirect or exponential methods.^{5,9}

The indirect method was used by Kinsey, Grant, Cogan, Livingood, and Curtis^{3,4} for data taken from the rabbit. Our treatment differs from theirs mainly in the more formal manner in which the exponential factors or constants are derived and interpreted. We are indebted to the paper of Merrell, Gellhorn, and Flexner⁵

* This work has been supported in part by a grant from the John and Mary Markel fund to the Wilmer Institute. Presented at the 16th scientific meeting of the Association for Research in Ophthalmology, Inc., Atlantic City, June, 1947.

and to that of Silversmit, Entenman, and Fishler⁹ for this approach.

Our result for the guinea pig is of the same order of magnitude as that of Kinsey and colleagues for the rabbit in that we estimate that the intrinsic sodium of the aqueous is renewed at the rate of one turnover every hour.

EXPERIMENTAL PROCEDURE

The methods of preparing a neutral solution of NaCl labeled with radioiso-

topotopes of sodium was again applied when the aqueous was collected. Blood was taken from the left heart by chest puncture. The blood was always sampled later than eight minutes after the intravenous injection of tracer sodium, at which time the labeled substance had reached a steady value in the circulating plasma (See Figure 2 taken from Merrell, Gellhorn, and Flexner⁵).

Tracer sodium is expressed in millimoles per kilo aqueous (A* = n*) or per kilo of plasma water (P*_{eq.}), in which the subscript "eq." refers to the steady-state value of tracer. To calculate A*/A*_{eq.}, the proportion of its equilibrium value attained by the tracer in the aqueous at the given time, it was noted that

$$\frac{A^*}{A^*_{eq.}} = \frac{A^*}{P^*_{eq.}} \left(\frac{P^*_{eq.}}{A^*_{eq.}} \right) = \frac{A^*}{P^*_{eq.}} f$$

in which $f = 0.93$ was averaged from several guinea pigs used in our previous work.⁷

dium (Na²⁴) and of sampling the aqueous and plasma are given in the preceding paper.⁷ Less than 1 cc. of labeled solution was injected into a foreleg vein of the guinea pig under brief ether anesthesia. The animal was allowed to recover and

tions or interpretations are to be made are shown in the first five columns of Table 1. The data from the aqueous are also plotted in Figure 1. On the ordinate, instead of plotting absolute concentrations of tracer, we place the proportion of its

equilibrium value attained by the tracer in the aqueous at the time of sampling.

It is not at once apparent how one may calculate the rate of entry of intrinsic so-

damental methods of studying these difficulties.

THEORY

In the first, the *direct method*, the

Fig. 1 (Wilde, Scholz, and Cowie). The dots represent the accumulated tracer sodium in the aqueous humor at given time after the intravenous injection of labeled sodium. The upper straight line represents prediction of labeled sodium by the direct method; the lower curve prediction by the indirect (exponential) method.

dium from the rate of accumulation of tracer in the aqueous. Several basic difficulties present themselves. For instance, the measured accumulation of tracer is not a true picture of one-way inflow since some of the tracer which has entered during a finite time will have left the aqueous by outflow. Thus curves for the accumulation of tracer tend to bend toward the horizontal as time elapses and to approach an asymptotic value (fig. 1).

Under *Theory* we will discuss two fun-

amount of tracer accumulated in the aqueous is measured only early after its intravenous injection during which time very little of the tracer which has entered the aqueous has been lost again by outflow. In the second, the *indirect method*, the secondary outflow of tracer is accounted for in the mathematical treatment itself.

THE DIRECT METHOD

In using a tracer substance to measure

transfer rate across a membrane, such as the plasma-aqueous barrier, it is assumed that tracer and intrinsic body substance are transferred across the barrier in quantities proportionate to their concentrations in the plasma bathing the barrier; that is:

$$\frac{P^*}{P} = \frac{\Delta n^*}{\Delta n}, \quad (1)$$

in which P^* and P are the molar concentrations of tracer and intrinsic substance in the plasma at a given instant and Δn^* and Δn are the number of moles of the corresponding substances which during this same instant pass across the membrane from the plasma into the aqueous humor.

This theory holds only for the instantaneous passage of an infinitesimal quantity of tracer Δn^* . Only on two conditions can it be extended to measurements of finite amounts of accumulated tracer n^* in the aqueous. First, over long enough periods of accumulation some tracer can be expected to leave the aqueous by normal channels of outflow. Error in n^* due to this is minimized by collecting aqueous as soon as practicable after the intravenous injection of tracer. Second, once the tracer has been injected, its concentration in plasma P^* is, until equilibrium is reached, continually declining. We must substitute an average value \bar{P}^* estimated from the area under a plasma time-concentration curve. Equation 1 with rearrangement then becomes:

$$\frac{n}{P} = \frac{n^*}{\bar{P}^*} \quad (2)$$

in which n^* is the number of moles of tracer accumulated in a gram of aqueous during the period of observation and n is the number of moles of intrinsic substance which have passed into and out of this amount of aqueous in the same time. It is customary to express this as a fraction of the total substance A , the concen-

tration, in a gram of aqueous. Thus, the fraction exchanged is n/A .

A number of substances reach a steady state or equilibrium ratio between plasma and aqueous. This can be symbolized as:

$$\frac{P}{A} = f \quad (3)$$

If Equation 2 be multiplied by Equation 3, the value P in the left terms divides out, leaving the useful relation:

$$\frac{n}{A} = \frac{fn^*}{P^*} \quad (4)$$

Division by time t during which tracer is allowed to accumulate gives the exchange or turnover rate:

$$k = \frac{n}{At} = \frac{fn^*}{P^*t} \quad (5)$$

THE INDIRECT METHOD

The turnover rate k of a given intrinsic substance in the aqueous humor of the eye is defined as $k = r/A$, in which r is the number of moles of the substance which move by exchange into or out of a gram of aqueous per unit time (note that $r = n/t$ in the notation for the direct method) and in which A is the concentration in moles of the substance in a gram of aqueous. Since A is a constant, it follows that the rate r of movement of substance into the aqueous is equal to the rate r of movement of substance out of a gram of aqueous.

Hence, at any instant beginning from the time of the intravenous injection, the rate of one-way entry of tracer into a gram of aqueous is equal (1) to r , the number of moles of substance entering the aqueous per unit of time multiplied by (2) the proportion of this which is tracer, P^*/P . Meanwhile, the rate at which tracer is leaving the gram of aqueous is equal (1) to r , the number of moles of substance leaving the gram of aqueous per unit time, multiplied by (2) the pro-

portion of this which is tracer, A^*/A .

Thus the net rate of accumulation of tracer is:

$$\frac{dA^*}{dt} = r \frac{P^*}{P} - r \frac{A^*}{A} \quad (6)$$

in which P and P^* are the moles of substance and tracer in a gram of water of the fluid bathing the plasma-aqueous barrier and A and A^* are the respective values for a gram of aqueous humor.

This equation is simplified by noting at once that r/A is the turnover rate k and that r/P can be expressed in terms of k . For most substances, $A/P = f'$ is a constant, an equilibrium ratio across the aqueous barrier. Thus r/P may be set equal to $r/A \times A/P = kf'$.

With these substitutions and rearrangements Equation 6 becomes:

$$\frac{dA^*}{dt} + kA^* = f'kP^* \quad (7)$$

During the first few minutes after intravenous injection of tracer, it remains unknown whether the concentration P^* of tracer presented to the aqueous barrier is (a) identical to that in the plasma or (b) whether P^* is some lower value due to dilution of tracer in a pool of interstitial fluid interposed between the plasma-bearing capillaries and the aqueous barrier itself.

The remainder of the discussion will be limited to a study of the data obtained by using radiosodium (Na^{24}) in the guinea pig.

In case (a) in which P^* is represented by plasma values of tracer sodium, an integral for P^* may be substituted into Equation 7 in a form taken directly from Merrell, Gellhorn, and Flexner.⁵ This is represented in the upper curve of Figure 2 for which $P^* = a e^{-bt} + P^*_{eq.}$ (see notation in legend of figure 2).

With this substitution, Equation 7 is a linear differential equation of the first order (ref. 1, p. 19). Integrating, solving

for the constant of integration, and rearranging after substitution of $A^*_{eq.} = f'P^*_{eq.}$, where $A^*_{eq.}$ and $P^*_{eq.}$ are equilibrium values for tracer sodium per gram of aqueous and per gram of plasma water respectively, gives:

$$1 - A^*/A^*_{eq.} = (1 + L) e^{-kt} - L e^{-bt} \quad (8)$$

in which $L = k/(k-b)$ times $a/P^*_{eq.}$ is a constant.

For case (b), it is desired that the integral substituted for P^* represents the concentration of tracer sodium actually present in the interstitial fluid bathing the aqueous barrier. During the first eight minutes, after the intravenous injection, while tracer sodium is rapidly entering the interstitial fluid from the plasma, the concentration in the interstitial fluid may first rise abruptly and then decline to equilibrium $P^*_{eq.}$. Such a situation would be complex to describe mathematically. We will consider the simplified case in which during the early eight minutes leading to equilibrium in the plasma the tracer which has left the circulating plasma up to any given instant is uniformly mixed in the total volume of interstitial fluid in the guinea pig. The equation for P^* in this situation can be derived either by simple visual inspection of the lower curve of Figure 2 or by a more formal treatment analogous to that used by Merrell, Gellhorn, and Flexner for the plasma curve.

If now this substitution, $P^* = P^*_{eq.} - P^*_{eq.} e^{-bt}$, is made into Equation 7, an integration procedure analogous to that used for Equation 8 yields the equation:

$$1 - A^*/A^*_{eq.} = (1 - M) e^{-kt} + M e^{-bt}, \quad (9)$$

where $M = k/k-b$ is a constant. (In this derivation, we neglect a Donnan ratio across capillary membranes and assume that the concentration of sodium in plasma water is equal to that in interstitial fluid water.)

RESULTS

THE DIRECT METHOD

The quantity of intrinsic sodium exchanged in the aqueous during an experiment (equation 4) is $n/A = f n^*/\bar{P}^*$. The ratio $f = P/A = P^*_{eq.}/A^*_{eq.}$ was measured in a separate experiment as an

sample of aqueous. \bar{P}^* is estimated as follows: The decline in plasma concentration of tracer sodium P^* from the time of intravenous injection until the equilibrium point, beginning in the plasma about eight minutes after injection, is shown in the upper curve of Figure 2. This curve from Merrell, Gellhorn, and Flexner will

Fig. 2 (Wilde, Scholz, and Cowie). The concentration of tagged sodium (P^* in counts per sec. per cc.) in plasma plotted against time after injection of Na^* into a foreleg vein of guinea pigs. The plotted data, the upper equation, and fitted curve are from Merrell, Gellhorn, and Flexner.⁶ The lower equation and curve represent concomitant "average" concentrations in interstitial fluid (see explanation in text). The transformation from our notation to that of Merrell *et al.* is as follows: $P^* = c_t$, the concentration of labeled sodium in the plasma. $a = c_0 - c_{eq.}$, in which c represents concentration of labeled sodium in plasma: c_0 , at zero time and $c_{eq.}$ at equilibrium in the plasma. As shown by the arrow at the left, a is the concentration of tracer in the plasma at zero time as an "excess" over the equilibrium value in plasma. b is the rate of loss in concentration of plasma tracer substance per minute relative to excess concentration. $P^*_{eq.} = c_{eq.}$. In the symbols on the chart dots are used as superscripts in place of asterisks to identify tracer (for instance $P^* = P^*$).

average from several animals in which tracer sodium was allowed 24 hours after intraperitoneal injection to reach equilibrium between the plasma and aqueous.⁷ In the rate experiment itself the value n^* is measured directly from the given

be called a "standard curve" and was fitted to points from a number of animals, each point being adjusted to an assumed or arbitrary standard dose of tracer sodium.

\bar{P}^* is the average concentration of

plasma tracer presented to the aqueous barrier during the period t allowed for accumulation of n^* amount of tracer. For the standard animal it would be the area under the curve divided by time t . This standard \bar{P}^* and the \bar{P}^* for an animal given a particular dose would be related

$f n^*/\bar{P}^*$ increases linearly with time the secondary loss of tracer from the fetus by outflow back to the mother is negligible. This early linearity for the aqueous is illustrated in Figure 3. It is not clear just where on the plot the linear period ends. Thus for reasons to be discussed later we

Fig. 3 (Wilde, Scholz, and Cowie). The direct or linear method. The apparent amount n/A of intrinsic aqueous sodium which had exchanged beginning from the intravenous injection of Na^+ until the stated time. Both circles and dots are experimental points but only the dots were used to calculate turnover rate, $k = f n^*/\bar{P}^* t$, as in Table 1. The average k value from these gives the slope of the continuous line drawn arbitrarily through the origin. This line is extended (broken) to show the divergence of later points (circles) because of outflow of tracer from the aqueous.

to each other as are the equilibrium concentrations P^*_{eq} of each.

Values of $n/A = f n^*/\bar{P}^*$ as calculated from Table 1 are plotted in Figure 3.

We have assumed in the studies of placental transfer rate done in this laboratory^{2,8} that as long as the value of

have arbitrarily chosen only points measured earlier than eight minutes after injection to calculate k from Equation 5 in which $k = f n^*/\bar{P}^* t$. The average k for the six animals chosen from Table 1 is 0.014 with a standard deviation of 0.003. This $k = n/At$, which is the turnover

rate, has been used as a slope to draw a line arbitrarily through the origin of Figure 3.

The turnover time corresponding to this k or slope would be $1/0.014 = 71$ minutes for a complete turnover of intrinsic aqueous sodium.

THE INDIRECT METHOD

Equation 8 predicts the value of $A^*/A^*_{eq.}$, the concentration of tracer in the aqueous at a given time as a proportion of the concentration in the aqueous at equilibrium. Values of $A^*/A^*_{eq.}$ estimated from the data of Table 1 are plotted in Figure 1. To fit the theoretical curve to these points the usual device a plot of $\ln(1 - A^*/A^*_{eq.})$ against time is considered. While this at first sight seems complicated by the presence of two exponentials, further examination reveals that one of these, that containing e^{-bt} , approaches zero at eight minutes, the time at which the plasma tracer approaches a steady value. Thus after eight minutes this term drops out and the log of the remaining part yields the linear relation.

$$\ln(1 - A^*/A^*_{eq.}) = \ln(1 + L) - kt \quad (10)$$

A plot of actual $\ln(1 - A^*/A^*_{eq.})$ values indeed demonstrates that the data fit such a linear relation for times later than eight minutes. A line fitted to these later points by least squares has the slope -0.016 which is the value of k or the turnover rate per minute. The standard error of estimate (ref. 6, p. 456) of this slope or rate is 0.001. The turnover "time" is thus $1/0.016$ or 62.5 minutes.

If the straight line portion of this log curve is projected leftwards to the y axis it has the intercept value $\ln(1 + L)$ as indicated in Equation 10. Thus $(1 + L)$ has the numerical value 0.86, which is the value of the coefficient of e^{-kt} in Equation 8. With $1 + L = 0.86$, $L = 0.14$, the coefficient for e^{-bt} .

There remains the calculation of the value of b . Since $L = k/(k-b)$ times $a/P^*_{eq.}$, in which $k = 0.016$ and $a/P^*_{eq.} = 4.525$, the latter being supplied by the paper of Merrell, Gellhorn, and Flexner,⁵ b is calculated to be 0.52.

After substituting into Equation 8 the various values for the constants which have been enumerated above we have,

$$1 - A^*/A^*_{eq.} = 0.86 e^{-0.016 t} + 0.14 e^{-0.52 t}$$

This equation was used to calculate points through which the lower curve of Figure 1 is drawn.

Equation 9 can be fitted by a device analogous to that used for Equation 8. When this is attempted, however, the fitted curve falls far below the experimental points. This implies that the early concentrations P^* of tracer at the functional aqueous barrier are nearer those of the simultaneous declining values in the circulating plasma itself than they are to the ascending values averaged for interstitial fluid as a whole.

DISCUSSION

Error in the direct method caused by tracer outflow. We have mentioned the effect upon the direct method of the outflow of tracer from the aqueous humor. We now show graphically how this error increases with time following the injection of tracer. The lower curve in Figure 1 shows the actual amount, as a fraction of equilibrium, $A^*/A^*_{eq.}$, of tracer in the aqueous at given times. This, as stated, was plotted from Equation 8 which accounts for outflow. The upper line, on the other hand, predicts the amount of tracer, expressed as $A^*/A^*_{eq.}$, which has entered the aqueous one-way, no account having been made for loss by outflow.

The distance between the curves in Figure 1 represents the error of the direct method due to outflow of tracer. At about eight minutes, when $A^*/A^*_{eq.} = 0.25$, when tracer in the aqueous has attained

one fourth of its equilibrium value, the aqueous will have lost by outflow an amount of tracer equal to 11 percent of the tracer in it at that time; when $A^*/A^*_{eq.} = 0.4$, the discrepancy is 24 percent.

In calculating k by the direct method we have thus arbitrarily chosen only points sampled before eight minutes so that the error of outflow would be kept below 10 percent. The direct method gave a k value of 0.014 compared to 0.016 by the exponential method.

The simplicity of fitting the exponential. As one or another experimental condition or agent is tested for its effect upon the turnover rate, it is possible that the agent will be found to change the shape of the plasma curve. To apply the direct method might thus involve the detailed construction of the plasma curve for each agent. To avoid this, as is possible in the exponential method, is a distinct advantage. In the latter method one merely determines approximately how early a steady value is reached by tracer in the plasma. Aqueous values determined later in time may then be plotted as $\ln (1-A^*/A^*_{eq.})$ to determine the slope $-k$, the turnover rate. If it is desired to draw the exponential curve, b can be calculated as previously indicated from the expression for L .

Aqueous values thus measured late in time are of greater magnitude and are more accurately measured than are the smaller early values required in the direct method.

However, warning must be given concerning the collection of data for calculating $A^*/A^*_{eq.}$ from A^* . We have shown in the legend of Table 1 that $A^*/A^*_{eq.} = A^*f/P^*_{eq.}$. Thus, the plotted value $A^*/A^*_{eq.}$ involves three errors: the error in A^* and that in $P^*_{eq.}$ for the particular animal and the deviation represented by the difference in f as averaged from a

series of animals and the f ratio for the particular animal. The effect of this summated error becomes particularly significant if $(1 - A^*/A^*_{eq.})$ approaches zero, at time near equilibrium. Then its \ln value experiences large deviation for small deviation in $A^*/A^*_{eq.}$. One should work with well-scattered points but along the middle range of the time course of the equilibration process for the aqueous.

The effect of early unknown time— P^ values on the direct method.* Precise application of the direct method requires accurate values at known times for the concentration of tracer sodium P^* in the interstitial fluid at the effective barrier to the anterior chamber. To avoid error from outflow of tracer, sampling of the aqueous humor must be done early after the intravenous injection of tracer. This is just the time, during the early decline of plasma tracer, when it is most difficult if not impossible to measure or calculate the value of tracer at the barrier. Furthermore, depending upon the particular channel postulated for the entry of sodium into the anterior chamber, there may be a considerable time lag between the passage of tracer across the barrier and its delivery into the anterior chamber where we sample and measure it. For instance, if sodium enters the aqueous by way of the ciliary body the time for travel from the ciliary body through the posterior chamber and pupil into the anterior chamber where sampled would constitute a considerable portion of the short period allowed for accumulation of tracer in the linear method. These constitute unavoidable errors in the direct method as applied to aqueous.

The indirect method, on the other hand, is deliberately applied late after the injection. At this time P^* is a steady value in the plasma and probably in the interstitial fluid and the posterior chamber, if this latter constitute a pathway of entry

of sodium into the anterior chamber. The slope of the \ln plot of $(1 - A^*/A^*_{eq.})$ constitutes a proven value for k the turnover rate as we have defined it. This k refers to the average rate of the continual passage of intrinsic sodium through a gram of aqueous in the anterior chamber irrespective of the number and nature of the various channels by which sodium may traverse that chamber. The rate is, of course, expressed as a fraction of the total amount of intrinsic sodium in the unit of aqueous.

In the exponential equation itself the effect of the early uncertain P^* values upon the delivery of tracer to the anterior chamber is summarized complexly in the constant L and the exponential factor b .

SUMMARY

The direct or linear is compared with the exponential method of calculating from tracer data the turnover rate of a constituent in the aqueous humor of the eye. In the former, outflow of tracer from the aqueous is ignored; it being minimized by measuring the tracer accumulated in the aqueous only early after its intravenous injection.

A double exponential equation is fitted which accounts for the outflow as well

as for the changing inflow of tracer which attends the declining plasma concentration that follows early after intravenous injection of tagged substance.

Tracer sodium tagged by radioactive (Na^{24}) was injected into the foreleg vein of guinea pigs. In six aqueous samples treated by the linear method the turnover rate was 0.014 ± 0.003 ; in 21 samples calculated by the exponential the rate was 0.016 ± 0.001 . The latter represents a turnover time of 62.5 minutes.

By comparison with the exponential it is shown that the error for the linear method due to outflow is 11 percent by the time the tracer has reached one fourth of its equilibrium value in the aqueous.

Other disadvantages of the linear method not encountered by the exponential as applied to aqueous include: uncertainty concerning the exact value of the early concentration of tracer at the functional aqueous barrier; the error of measuring *small* amounts of accumulated tracer early after the injection; the necessity of precise construction of plasma time-concentration curves for tracer.

DISCUSSION

DR. VESEY (New York): I would like to ask the speakers if they made any efforts to observe the route of the out-

flow of the aqueous tracer substances from the anterior chamber.

Many arguments could be brought up.

Dr. Troncoso has beautifully shown that the lower animals, on which the experiments are usually carried out, do not have a structure resembling the human ciliary body. He showed that carnivora and rodentia do not have a ciliary body similar to that of human beings. They have a spongy tissue in the ciliary body, and this is the organ that carries the outflow of the aqueous in these animals. In human beings, as I said, many arguments could be brought up against the idea of the ciliary body being the main organ of the outflow, and if any research workers make any efforts to show the route of the outflow, I think our knowledge of the physiology of this very important subject would be enhanced quite a bit. I would like to hear something about that.

DR. WILDE: Well, we have one provisional observation that bears on that question. We have observed, in studying the rate of sodium flow into the lens, that the lens appeared to pick up more sodium than it should had it been bathed in tracer as we measured it in the anterior chamber. In other words, the lens had early been exposed to a tracer concentration higher than that found in the anterior chamber.

This could mean that an early rich batch of tracer was being delivered to the posterior chamber of the eye, and that this rich material was bathing the lens. Of course, it is to be admitted that sodium may have been crossing from the vitreous behind—not saying how quickly it may enter the vitreous. Dr. Scholz may have other comments in this regard.

DR. SCHOLZ: The only other thing that I have to add is that the technique we were using was not directly adaptable to determining the route of outflow—there are other radioactive techniques that might be used but we have not as yet employed them.

DR. DUNNINGTON: Are there any other questions?

DR. WILDE: One other comment in regard to the possible path of flow of tracer into the anterior chamber is that we have entertained the possibility that if the tracer did come by way of the ciliary body, there would be a considerable lag in time as this material went from the ciliary body to the anterior chamber by this pathway.

If I may refer to Slide 6 again, you will see that there is a suggestion of a peculiar early delay. This is only a very provisional type of data, however, in an animal as small as the guinea pig, and when the samples are so small. There is an indication of some delay; perhaps, low values, too early in time, or a tendency to pile up here. Dr. Friedenwald lately has entertained another equation in which it is attempted to account for a stepwise flow of tracer from, say, ciliary body to posterior chamber, and from posterior chamber into anterior chamber, having three exponentials in attempting to explain a problem of that sort. We are greatly indebted to Dr. Louis Flexner and Dr. Jonas Friedenwald for their advice, encouragement, and assistance with this work.

THE SODIUM-VAPOR LAMP AND ITS USE FOR REFRACTION*

STEFAN VAN WIEN, M.D.
Chicago, Illinois

The use of selected portions of the spectrum in ophthalmology is not new. It was early evident that the ill-defined appearance of the eyeground by "white" light was due, in large extent, to the chromatic aberration of the human eye. This led inevitably to elimination of more or less of the polychromatic character of the illumination to obtain an improved fundus picture for certain specific details.

As early as 1903, Mayou¹ employed the mercury-vapor lamp. Vogt² utilized the carbon arc, supplemented by elimination of the infrared end through use of a 30-percent copper-sulfate solution with an added 1 percent of erioviridin to remove the visible red and orange. Friedenwald³ also advocated the use of the carbon-arc lamp and introduced a filter to eliminate all but the yellow and green. Cousin⁴ and Bichelon⁵ further limited the spectral range through filtration of an incandescent tungsten filament to hold the light source at about 5,800 A. U. The first use of sodium light as a monochromatic source occurred with Kleefeld,⁶ in 1935. In all of these various spectral range selections, the light may be considered as "red free," but this is obviously a term of great freedom.⁷

Mayou's mercury-vapor lamp is completely red free but quite rich in the short blue and violet. Under it the fundus appears bluish gray, and the retina, because part of the transmitted spectrum is absorbed and part reflected in a diffused manner, appears largely opaque. Deeper structures cannot be seen as distinctly as

is possible with more nearly monochromatic illumination.

Vogt established the carbon arc together with filtration of the infrared, red, and orange regions, to demonstrate the presence of the yellow pigment of the macula lutea in the living eye, and not solely as a postmortem phenomenon. As late as 1924, his "red free" light was still being used almost exclusively as a selective source of illumination.

Friedenwald in that year believed that "the full value of the control of spectral range of the light used in ophthalmoscopy has not yet been realized." He decided on the use of yellow light because this light is most strongly reflected from the fundus.⁸ For his purpose, it proved advantageous to include some of the yellow-green portion of the wave band to enhance the visibility of certain fundus structures. Friedenwald's filter was a solution of aniline green Naphthol B in glycerin, and with the resultant illumination, the eyeground appeared yellow green, the venous blood as black, and the arterial blood as dark gray. After adaptation, connective-tissue streaks, vessel walls, and exudates appeared in shades bordering on white.

Cousin, Monnier, and Mouton,⁴ in 1933, attempted to prove that yellow headlights on automobiles were superior not only to penetrate fog, but for increased visibility in clear atmosphere. They demonstrated that a certain black object which could be recognized at 130 meters with ordinary headlights was visible at a distance of 160 meters with their selective light. Their bulb contained a tungsten filament at 2,800°C. The filter, consisting of cadmium-sulfate solution, transmitted nearly monochromatic (98 percent) light of 5,820 A. U.

*From the Department of Ophthalmology, Northwestern University Medical School. Aided by a grant from B. Spero for the Sanford R. Gifford Memorial Fund. Read at the meeting of the Chicago Ophthalmological Society, May 19, 1947.

These investigators also used their bulb as illumination for a test chart provided with Snellen letters and Landolt broken circles to ascertain if this light increased visual acuity as well as improving visibility. They reported a 10-percent increase in visual acuity but did not detail how they had arrived at this figure; they also were under the impression that the eye would not so easily become fatigued under yellow illumination, and that its use in factories where detail work had to be done would therefore be advantageous.

In conclusion, they stated that selective yellow light could serve a twofold purpose to the ophthalmologist. It would be superior as source of illumination for test charts, as well as an ophthalmoscopic lamp, since it was less annoying when used for focal illumination. Moreover, the pupil did not contract as much as with ordinary light, and, consequently, fundus details could be made out more easily when a mydriatic was not used. The same light also proved superior for fundus study in cases with cloudy media because of its greater penetrating power.

Bichelonne, Favory, and Bégue⁵ repeated some of the investigations just discussed. Once more, they reported visual acuity increased one tenth, and, again, no specific data as to how they arrived at that figure. They believed the increased visual acuity to be explained by the fact that yellow light omitted the short end of the spectrum. André Broca⁹ had previously demonstrated the increased retinal fatigue accompanying the shorter wave lengths; according to his work the optimum wave length for minimal fatigue would be 5,600 Å. U.

With yellow light as source of illumination, fundus details appeared much more distinct; in particular, the retinal vessels stood out very clearly as did retinal and choroidal changes. These authors also believed that there should be gratifying re-

sults with vitreous opacities, but published their article before substantiating that belief clinically.

Although the filters in all these investigations provided fairly monochromatic yellow light, it is surprising that the sodium-vapor lamp had not been employed before as the one light source that filled, most ideally, this requirement. Certain forms of this type of lamp were available for more than a decade, the first attempts reaching back to 1919 when A. H. Compton of the Westinghouse Company applied for a patent.¹⁰ Kleefeld⁶ had been experimenting with infrared light and its application to fundus study. Technical reasons slowed up his progress and, in an endeavor to turn his research efforts into more promising fields, he was the first one to employ the sodium-vapor lamp in ophthalmology, investigating its possible advantages for focal illumination, retinoscopy, examination with the plane mirror, indirect and direct ophthalmoscopy, and photography of the anterior segment. So far as retinoscopy was concerned, the reflected light appeared grayish white. The reflex was very distinct and one was not forced to observe it in the area of the disc, as in retinoscopy with ordinary light. It was quite easy to perform retinoscopy in the foveal region (obviously, Kleefeld performed his retinoscopies without cycloplegic).

This author's statements are quite enthusiastic, listing numerous advantages, and possibly creating the impression that he would prefer to replace the ordinary polychromatic light with the sodium lamp.

Serr,¹¹ who repeated some of Kleefeld's studies, was much less enthusiastic in his conclusions. He found the direct method of ophthalmoscopy unsatisfactory (naturally he had to use a nonilluminating type of ophthalmoscope), and his findings are based on results obtained by indirect ophthalmoscopy.

Serr reported that where opacities of the refractive media existed, it was still possible to obtain a fairly distinct view of the fundus where polychromatic light allowed only a vague glimpse. This characteristic of sodium light was expected, since the refracting media become more transparent as the wave length increases.¹² Furthermore, sodium light was particularly suited to old people since the yellow-brown discoloration of the lens did not absorb this light to any extent. Of course, even sodium light did not permit visualization of the eyeground where the opacities exceeded a certain intensity.

Serr further reported that in instances of corneal scars, fresh infiltrates of the cornea, extensive deposits of keratic precipitates in uveitis, exudates, and fibrinous deposits on the anterior surface of the lens, as well as vitreous opacities and hemorrhages, surprisingly many fundus details could be seen with sodium light against only an indistinct outline of the optic disc with white light. Serr found that sodium light penetrated living tissue, like the pigment epithelium, making choroid vessels appear distinct. There was a wide zone missing in the yellow portion of the absorption spectra of hemoglobin and oxyhemoglobin. Since, ordinarily, their walls were transparent, the retinal veins and arteries appeared black or gray respectively. For this reason, irregularities in the caliber and formation of anastomoses were brought out very distinctly. Likewise, hemorrhages and pigment deposits stood out very clearly—although it was not possible to differentiate them by their color but only by their configuration. In retinal detachment, a tear, appearing gray, could readily be differentiated from the black of a hemorrhage. Unlike the red-free light of Vogt, sodium light did not allow observance of the yellow color of the macula lutea.

With this light the retina was complete-

ly transparent, there were no reflexes, and not even the nerve fibers could be traced. The choroid absorbed a large part of the light; whatever portion reached the sclera was reflected and underwent further absorption on its return passage giving the choroid a grayish appearance. Serr observed evidence of choroidal hemorrhages in almost every case of severe contusion of the globe which could not be visualized by other means—not even the “red-free” light of Vogt.

Ballantyne,¹³ during a visit of the British Ophthalmological Society to the Research Laboratory of G. E. C. Wembley in 1936, became acquainted with the sodium-vapor lamp and its possible use for ophthalmoscopic work. His conclusions, drawn from investigations made simultaneously but without knowledge of that by Kleefeld, were most complete and illuminating. His report agreed with those of other authors already mentioned, except that, contrary to Serr's statement, Ballantyne was under the impression that the course of the nerve fibers radiating from the disc could usually be fairly clearly traced. He stressed very emphatically that color values could not be appreciated in sodium light. The pigmentary changes in myopia, for example, were transparent, and a melanoma of the choroid disappeared under sodium light.¹⁴

Glueck,¹⁵ contrary to a majority of opinions, believed that corneal opacities, as a rule, would not become more transparent with sodium light. Those resulting from interstitial keratitis were the exception, and he considered this fact as of almost diagnostic significance. Glueck did not mention a universal increase in visual acuity, but noted that patients with opaque media could see better when test types were illuminated with sodium light. He usually succeeded in enabling the patient to gain “a degree” in reading the test types by use of sodium light. He further

stated quite emphatically that he could see no advantage of sodium light in ski-ascopy but neglected giving reasons for these conclusions which were exactly contrary to Kleefeld's experience.

From the discussions so far, it is quite evident that in none of the previous investigations was the primary object to study the possible implications of the use of sodium light as a source of illumination in retinoscopy. Illumination of the test objects was done only in a very cursory manner. There was only a certain curiosity to see "what would happen" if sodium light was used. It is surprising that sodium light has not been investigated more thoroughly in connection with retinoscopy since, for theoretical reasons that have not heretofore been stressed, it seems to be singularly suited for this.

The human eye is not an achromatic optical instrument, as was first noted by Wollaston, in 1801. The amount of chromatic aberration has been variously reported as 1.3D. by Young, 1.5 to 3.0D. by Fraunhofer, and 1.8D. by Helmholtz.¹⁶ Under ordinary conditions, this aberration does not interfere with clear vision; in fact, it requires special arrangements to demonstrate this phenomenon.

In ordinary daylight, the human eye supposedly focuses for the yellow part of the spectrum.¹⁷ Thus it is myopic for the shorter wave length of the spectrum and hyperopic toward the red end. The most widely accepted explanation for this is that the yellow part of the spectrum is appreciated subjectively as its brightest portion, and that, in decreased illumination, relative brightness shifts toward the yellow-green region. A number of subjective methods for refraction are based on the chromatic aberration; for instance, the cobalt-glass test and its various modifications, and Brown's duochrome test. The principle of these tests is to offer two fields, the one illuminated by shorter, the

other by longer, wave lengths than the yellow. It is impossible to have both fields in focus simultaneously. However, when both of them appear equally distinct—more correctly, equally blurred—the yellow supposedly is in exact focus. These methods are widely used among refractionists, and have proved to be valuable assets. Yet it seems that it would be more logical and more practical to use light of the specific wave length in which we are interested than to obtain our result by "interpolation."

In retinoscopy, interpretation of the refractive state of the eye is based on that portion of the spectrum that is reflected from the fundus; that is, light above 5,760 Å. U.¹⁸ Still that leaves a large portion of the spectrum subject to a chromatic aberration of possibly one diopter. Furthermore, subjective vision should be more distinct with sodium light as the source of illumination, and it should be much easier for the patient to decide exactly what spherical correction gives the best visual acuity. If this holds true for distance vision, it should be even more decisive at close range. Whereas the patient has to accommodate for the exact distance at which the test chart is presented when only monochromatic light is available, it is possible that with polychromatic illumination little or no accommodation is called into action if the violet portion of the light reflected from the reading chart is utilized at reading distance.

In an emmetropic eye (or one that is made emmetropic by correcting lenses) the punctum remotum for the short end of the spectrum is approximately 23 inches, which means that only $\frac{3}{4}$ myodioter of accommodative effort would enable an individual to read at 16 inches with complete comfort. For the same result $2\frac{1}{2}$ myodioters of accommodation are required for the sodium line of 5,900 Å. U.

It is known that there is such a phenomenon as "paradoxical" accommodation. Patients with aphakic eyes surprisingly often are able to read quite well at close range with their distance correction. The interpretation for this phenomenon is that these eyes utilize the violet end of the spectrum.

The investigations about to be discussed were undertaken to determine whether or not elimination of chromatic aberration would bring about improvement in our present method of refraction.

PROCEDURE OF INVESTIGATION

SOURCE OF LIGHT

The Gates sodium-vapor unit, manufactured by the George Gates Company in Long Island City, New York, was selected as the source of light. The model equipped with a reflector for illumination purposes was used and, when further provided with a metal screen with a small hole in the center, served as retinoscopy light for a nonluminous retinoscope as well (fig. 1).

Strictly speaking, this lamp is not monochromatic, but the maximum output is between 5,889 and 5,895 Å. U. Some of the other wave lengths emitted fall outside the visible spectrum, and need not be considered here. The remaining 2 percent of the visible spectrum can be neglected as insignificant. The light is very brilliant; it produces about 650 lumen after a brief warming-up period, and will deliver approximately 300 foot-candles at one foot. This illumination is in excess of what is considered adequate. However, visual acuity is little influenced by intensity of illumination within wide limits.¹⁸ An ordinary 25-watt electric bulb served as source of polychromatic light for the control tests, and, by varying the distance of both sources, the amount of reflected light from the visual-acuity chart could

be adjusted to two foot-candles for either light.

METHOD

There were 55 patients, ranging in age from 12 to 56 years and averaging 29 years. Most of them were university students, and excellent cooperation was ob-

Fig. 1 (Van Wien). The Gates sodium-vapor lamp and the cover (A) used to convert it into a retinoscopy lamp.

tained when subjective tests and discrimination of details were involved. Two drops of 2-percent homatropine and one drop of 1-percent paredrine were used, and the examination started approximately one hour after instillation of the last drop.

1. Retinoscopy was performed with sodium light, and the procedure repeated with polychromatic light. The exact distance of one meter was marked off to eliminate any possible discrepancy in find-

ings due to an error introduced by performing the retinoscopy at different distances. No attempt was made to determine the point of neutralization, but the first lens that would reverse the movement of the shadow was noted. A plain mirror served as retinoscope.

2. The test was performed by deducting one diopter from the retinoscopic find-

4. The postcycloplegic test was performed 5 to 8 days later. First, white light was used, and every effort made to obtain the best possible visual acuity. Only then was it determined whether there was the same, better, or poorer vision with sodium light. Again, every effort was made to improve the vision by changes in the spherical correction.

TABLE 1
RETINOSCOPIC FINDINGS FOR SODIUM AND POLYCHROMATIC LIGHT

+ $\frac{1}{2}$ D. More With Polychrom. Light	+ $\frac{1}{2}$ D. More With Polychrom. Light	Identical Findings	+ $\frac{1}{4}$ D. More With Sodium Light	+ $\frac{1}{2}$ D. More With Sodium Light	Total
5 (4.5%)	29 (26.4%)	72 (65.5%)	3 (2.7%)	1 (0.9%)	110 (100.0%)

ings that were obtained by both sources of light. The Snellen chart was first illuminated by polychromatic light and then by the sodium-vapor lamp. If there was a discrepancy between the retinoscopic findings for white and yellow light, both values were used with both sources of illumination. No change was made in the cylindrical correction but, if the visual acuity could be improved, changes in the spherical values were made, and the correction that would give the best visual acuity recorded.

3. In every instance, an attempt was made to determine the "punctum proximum," that is, the closest distance at which the smallest print could be read. If possible at all, the same size print was used for yellow and ordinary light. Quite frequently, however, a smaller size print could be read at a closer distance with one source of light than a larger size at a farther distance with the other. In this way, the determined values were still of a qualitative, though not quantitative, significance. The distance correction that gave the best visual acuity was worn for this test.

5. The punctum proximum was determined for white and yellow (the distance correction was worn by the patient for this test).

It appeared more appropriate to evaluate the objective results according to individual eyes rather than patients because, in most instances, there was a difference between both eyes.

The retinoscopic findings, both for polychromatic and sodium light, were almost identical. The slight differences are tabulated in Table 1.

The subjective results—both visual acuity and preference for either form of illumination—depend to some extent on the judgment of the patient. Allowance should be made for some uncertainty in discriminating small details when dealing with untrained observers. Of the group, 70 percent gave excellent coöperation; 14 percent were hesitant but did not contradict themselves; and 16 percent contradicted themselves more than once, but did not have to be excluded as unsatisfactory. Of the total of 55 patients, six did not return for a postcycloplegic test. Thus, complete data are available for 49

cases concerning the subjective test under both cycloplegic and postcycloplegic examination.

RESULTS

In presenting the results for the near test it must be considered that their value under cycloplegia is open to criticism. It was reasonable to expect that with the eyes under the influence of cycloplegia, one would be unable to read even large print at a rather short distance. Therefore, it was surprising to note that most patients were able to read relatively small print at a fairly close range. Possibly the strength and amount of homatropine used

as follows: The "near point" was identical for nine of them under both forms of illumination, slightly closer for two under sodium light, and definitely closer for 12 under white illumination. For the determination of the actual near point during the postcycloplegic test, patients requiring presbyopic correction were excluded, leaving a total of 44 cases. The near point for white and sodium light was identical for 41 of these and only slightly closer under white illumination for three.

COMMENT

According to all investigators of the subject, there seem to be definite advan-

TABLE 2

SUBJECTIVE PREFERENCE AND VISUAL ACUITY FOR CYCLOPLEGIC AND POSTCYCLOPLEGIC TESTS

	Subjective Preference	*Better Visual Acuity
White for cycloplegia and postcycloplegia	0	0
Sodium light for cycloplegia and postcycloplegia	21	6
White for cycloplegia, Sodium light for postcycloplegia	2	0
Sodium light for cycloplegia, White for postcycloplegia	3	0
No preference for cycloplegia, Sodium light for postcycloplegia	5	3
No preference for cycloplegia, White for postcycloplegia	5	3
Sodium light for cycloplegia, No preference for postcycloplegia	8	5
White for cycloplegia, No preference for postcycloplegia	1	1
No difference for cycloplegia or postcycloplegia	4	31
<i>Total</i>	49	49

* Visual acuity was considered "better" if one or both eyes could see at least four additional letters.

was insufficient to effect complete cycloplegia. Nevertheless, although there was some residual accommodation left, the figures were, at least, of relative value, inasmuch as there was considerable interference with the accommodation. Only a small number could not be tested at all because the cycloplegia was so complete that they were unable to read even the largest print of the near test chart at closer than 40 inches under either form of illumination. Five patients were excluded because their answers varied—possibly due to a clonus of the ciliary muscle. The data for the remaining 28 subjects were

tages in the use of sodium light for ophthalmoscopy. However, the pathologic changes that could be examined most advantageously with this form of illumination were minute, and could be seen with much greater ease in direct ophthalmoscopy. The sodium lamp, in its present form, is well adapted as a source of light for indirect ophthalmoscopy. In direct ophthalmoscopy, the self-illuminating ophthalmoscope has so many advantages that it seems doubtful whether ophthalmologists, even to obtain added information about minor details, could be induced to resort to the rather cumbersome tech-

nique of using reflected light. It is obviously impossible to incorporate a sodium lamp into the head of the customary hand ophthalmoscope. To incorporate a sodium lamp into a Gullstrand type of binocular ophthalmoscope does not present insurmountable difficulties, but would add another costly piece of equipment to the already vast instrumentarium of the oculist. The relatively few advantages that can be expected hardly justify the recommendation of such an instrument, even for large clinics.

The sodium lamp is an ideal source of monochromatic light since for all practical purposes it emits only the D1 line of 5,897 and D2 line of 5,891 Å. U. It is also within the fraction of the spectrum that is reflected from the choroid. So it is not surprising that it was chosen as a very convenient and eminently practical source. Still, other forms of monochromatic light would have been just as suitable. It could be argued that thallium, with its single emission line in the green part, would be just as satisfactory. There are other emission spectra (especially if used with filters) that could be mentioned.

Retinoscopy, if performed with monochromatic light, of necessity requires that exact wave length for which the eye supposedly is focused. Sodium light fulfills this prerequisite as we know it and should, therefore, be the ideal source of light for retinoscopy if any advantage is obtainable from use of monochromatic light.

No different results could be expected from those obtainable with polychromatic light but it was anticipated that the point of neutralization or reversal would be more distinct with sodium light. This expectation, in the author's experience, did not materialize—an unexpected and entirely disappointing result.

On the contrary, retinoscopy with polychromatic light was just as distinct, and

no advantage whatsoever could be discovered by using sodium light. As indicated in Table 1 results were identical in 65.5 percent of the cases. In 31.0 percent of the cases, there was a tendency towards the positive side with white light, but in 26.4 percent, this difference amounted to only $\frac{1}{4}$ diopter, and to $\frac{1}{2}$ diopter in only 4.5 percent of the cases. In 3.6 percent, the findings tended toward the positive side with yellow light, the difference amounting to $\frac{1}{4}$ diopter in 2.7 percent. Although precautions were taken to perform the retinoscopy at exactly one meter, a difference of $\frac{1}{4}$ diopter was still considered within the limits of possible error. This leaves only six cases (5.4 percent) with a difference of $\frac{1}{2}$ diopter—a surprisingly small number. Of 38 eyes that showed variations, 27 (24.5 percent) accepted the findings obtained with white light, 11 (10.0 percent) those for sodium light. In other words, if any conclusions could be drawn at all, findings with polychromatic light were slightly more accurate.

For the postcycloplegic test, this tendency was slightly reversed to favor sodium light. It was interesting to note that quite a number of patients subjectively preferred sodium light. This might have been partly because the contours are somewhat softer with the latter, partly because the patients, although unaware of the purpose of the examination, were overly eager to cooperate, and decided in favor of the novel and unusual form of examination.

Of the 49 cases with complete data for cycloplegic and postcycloplegic tests, 21 (42.9 percent) expressed preference for sodium light on both occasions. This contrasts with six patients (12.3 percent) who actually showed better visual acuity. None of them expressed preference—or showed increased visual acuity—for

polychromatic light on both occasions. The 31 (63.3 percent) who showed no actual difference in visual acuity, contrast with 21 (42.9 percent) who, subjectively, preferred sodium light and four (8.2 percent) with no subjective preference for either light during cycloplegic and post-cycloplegic tests. The remainder of the results in Table 2 are within such limits as can be expected from an investigation of this kind, and, consequently, require no further comment.

The question as to whether there is a selective accommodation for a specific portion of the spectrum is quite involved, and cannot be answered by conclusions that are based on only one particular wave length. However, it is felt, if such a phenomenon actually exists, the findings, even for this one particular wave length, would demonstrate such a tendency. No such tendency existed with the accommodative mechanism intact.

Of 44 cases, 41 (93.2 percent) had the identical near point for white and yellow. However, of 28 patients whose accommodation was paralyzed (or at least greatly impaired) by the cycloplegic, 12 (42.85 percent) showed a definitely closer "near point." This is more than a coincidence, and is regarded as additional proof for the actual existence of "paradoxical accommodation."

A number of patients whose visual acuity was less than normal, were tested with white and yellow light. Some of these patients had only refractive errors. In others, the vision was actually impaired by opacities of the media. In all of these, the visual acuity was better with sodium than with polychromatic light. It is reasonable to assume that the improvement was due to the elimination of the chromatic aberration. This is an analogy to the improvement of vision by means of a stenopaic disc, and to the elimination of

spheric aberration. Possibly, this may explain why a small number of patients actually had better vision with sodium light, namely, there may have been a slight error in their refraction, which if corrected, would have caused identical visual acuity for white and yellow.

Just as much as spheric aberration is not corrected by the wearing of stenopaic spectacles, sodium lighting is not the answer to the elimination of chromatic aberration. So far as these investigations indicate, no advantage is obtained through the use of the sodium lamp for interior illumination; where improved visual acuity has resulted from installations of this nature, it is believed that closer investigation would have disclosed errors of refraction which if corrected would have provided equal visual acuity under polychromatic illumination.

SUMMARY

1. Certain advantages for funduscopy with sodium light reported by previous investigators are enumerated. These advantages are due to the greater penetrating properties of monochromatic light.
2. Results of retinoscopy, both with sodium and polychromatic light have been compared. No essential difference was encountered, and no advantages could be discovered in favor of sodium light.
3. With proper corrections, no increased visual acuity could be observed with sodium light.
4. With the ciliary mechanism intact, no evidence was noted that there is selective accommodation for the yellow portion of the spectrum.
5. Under cycloplegia, print can be read at closer distance with white light, and this may be additional proof for the so-called "paradoxical accommodation."

INTRAEPITHELIAL EPITHELIOMA OF THE CORNEA AND CONJUNCTIVA (BOWEN'S DISEASE)*

BENJAMIN ESTERMAN, M.D., JOSEPH LAVAL, M.D., AND
CLARA OKRAINETZ, M.D.
New York

The clinical and pathologic entity on which the condition known as intraepithelial epithelioma is based was first described in two cases of chronic skin tumor by the dermatologist, Bowen,¹ in 1912, as a precancerous dermatosis. Since then, many reports of similar lesions in both skin and mucous membrane have appeared, and the condition has come to be known as Bowen's disease. In 1939, Stout² wrote an excellent summary of the cases in the dermatologic literature and, in 1940, Cippollaro and Foster³ similarly reviewed the reported cases of mucosal lesions.

It remained for McGavie⁴ to recognize this condition in tumors of the cornea and conjunctiva and, in 1942, he published a report of five cases with clinical and gross and microscopic studies. The characteristic lesion on cornea and conjunctiva which he described consists of "slightly elevated, diffuse, sometimes multiple, highly vascular patches of reddish-gray gelatinous tissue—which arise from epithelium and may remain entirely within the epithelium for years without breaking through the basement membrane to show the usual tendency of epitheliomas to invade or metastasize."

Microscopically, these tumors showed loss of an orderly arrangement of the epithelial cells, which were hyperchromatic and variable in size with mitotic figures and giant cells containing either clumped nuclei (Bowen cells) or a single

giant nucleus; intact basement membrane, and a degree of inflammatory reaction in the submucosa.

Complete surgical excision was given as the treatment of choice, and radiotherapy was quoted as being contraindicated in the opinion of some pathologists, but McGavie did dwell on the difficulties of complete excision short of enucleation where the conjunctiva is also involved.

A sixth case was reported by George Wise,⁵ in 1943.

A seventh case of Bowen's tumor of the conjunctiva was reported by Khanolkar,⁶ in 1946. Repeated excision resulted in recurrences, of which the last showed malignant changes. Radium application was followed by no recurrence for the remaining four years of this patient's life.

CASE REPORT

P. G., a 63-year-old Puerto Rican woman, was admitted to the Eye Clinic of the Manhattan Eye, Ear, and Throat Hospital, service of Dr. R. T. Paton, on May 21, 1946, with a history of growth on the right eye of five months' duration. There was no previous history of ocular injury or inflammation.

Eye examination. The left eye was normal, with clear media and negative findings for the fundus. Visual acuity was 20/40 with the illiterate chart, due principally to poor coöperation. The right eye showed a visual acuity of 10/200, which could not be improved. The bulbar conjunctiva was slightly injected. In the lower nasal quadrant of the cornea and crossing the limbus was a mass (fig. 1), about 5 mm. in diameter and elevated

* From the Eye Department (Service of Dr. R. T. Paton) and the Radiotherapy Department of the Manhattan Eye, Ear and Throat Hospital. Read before the New York Society for Clinical Ophthalmology, February 3, 1947.

about 1 mm. It was pinkish gray in color, with a slightly granular surface and the texture of a cauliflower. In the surrounding cornea, including the pupillary area, there was a faint grayish infiltrate, and the bulbar conjunctiva and episclera immediately adjacent to the tumor were

Fig. 1 (Esterman, Laval, and Okrainetz). Intraepithelial epithelioma of the right cornea and conjunctiva before radiation.

more congested than the remainder of the eye. There were no keratic precipitates, cells, or flare. Ocular tension was soft. Dilation of the pupil revealed a faint, posterior, cortical lens opacity and a clear vitreous. The fundus was not perfectly visualized, but there was no gross pathologic condition. There were no palpable regional lymph nodes.

Physical examination. The general physical examination was essentially negative except for a soft systolic murmur at the cardiac apex; and slight transverse cardiac enlargement; blood pressure was 144/86 mm. Hg, urine was normal, Wassermann and Kahn tests were negative; blood sugar was 125; X-ray studies of skull, lungs, and long bones showed no evidence of tumor or erosion.

Laboratory report. On May 23, 1946, a portion of the tumor was excised for biopsy. The report by Dr. Joseph Laval follows:

"The low power (fig. 2) shows proliferation of the epithelial cells without any involvement of the corneal stroma or any other ocular layers. There is no inflammatory reaction and no hemorrhagic factor. The mass has a fairly well-defined external limiting surface with no evidence of necrosis or secondary infection. The high power (fig. 3) shows the basement membrane well defined, with no break through of any of the epithelial cells. Occasional mitosis is present. There are no pearl formations, or evidence of keratinization. No giant cells are seen and no so-called "monster cells" are present. The picture is typical of Bowen's intra-

Fig. 2 (Esterman, Laval, and Okrainetz). Low-power photomicrograph of biopsy; intraepithelial epithelioma of right cornea.

epithelial tumor in all respects except that no monster cells were found. I do not know whether the absence of monster cells is enough to throw out the diagnosis of Bowen's tumor of the cornea, but because the remainder of the picture is typical, I am inclined to consider this case one of Bowen's tumor."

Treatment. Since the tumor involved conjunctiva as well as cornea, it was de-

Fig. 3 (Esterman, Laval, and Okrainetz). High-power photomicrograph of biopsy: intraepithelial epithelioma of right cornea.

cided to attempt radiation. Accordingly, beginning May 29, 1946, under the direction of Dr. Okrainetz, the patient received nine treatments of low voltage unfiltered X-ray therapy in fractionated doses of 600r. every other day for a total of 5,400r. in 18 days. Under pontocaine anesthesia the lesion was screened off with lead foil leaving an exposed area of 1.5 by 1.5 cm. Using 60 K.V.; 5 Ma.; no filtration; target skin distance 10 cm.; H.V.L.: A1-0.4 mm.; output 610r. per minute, each treatment lasted 1½ minutes.

During the course of therapy, the patient had moderate hyperemia of the bulbar conjunctiva and slight pain which was promptly relieved by boric-acid ointment. After a few exposures, the lesion became thinner and at the end of the

course of treatments the tumor had entirely disappeared.

Results. On July 30, 1946, six weeks after completion of radiotherapy, the right eye was white except for a barely perceptible injection of the bulbar conjunctiva in the lower nasal segment of the globe. The tumor mass on both the cornea and the conjunctiva had melted away completely (fig. 4) leaving only the faint infiltrate previously seen and a few small deep vessels originating from the limbus. On the surface of the cornea, at the site of the growth, there remained a very shallow depression, 0.5 mm. at its deepest point.

Dilation of the pupil revealed no increase in the lens opacity noted prior to radiation. Ocular tension had remained soft. Visual acuity was unchanged.

Fig. 4 (Esterman, Laval, and Okrainetz). Reproduced from a Kodachrome of the right eye taken after completion of the radiotherapy.

In November, 1946, the condition was unaltered, except for a slight increase in superficial vascularization originating from the limbal vessels at the tumor site, resembling a pseudopterygium. The most

recent examination (September, 1947) shows this condition to have remained substantially the same, with no lens changes.

CONCLUSION

This case will, of course, require a longer follow-up period before any conclusions can be drawn as to the efficacy of radiotherapy. It is presented with the thought that it may stimulate others to be on the watch for this type of tumor, which otherwise might be considered basal- or squamous-cell carcinoma, papilloma, or simple hyperplasia; and that, if this form of therapy should prove successful, it may provide a more effective method for treating this type of growth in which there is involvement of the conjunctiva as well as the cornea.

OCULAR CHANGES IN ACUTE DISSEMINATED LUPUS ERYTHEMATOSUS*

REPORT OF A CASE WITH MICROSCOPIC FINDINGS

FREDERICK C. CORDES, M.D., AND SAMUEL D. AIKEN, M.D.[†]
San Francisco, California

A report of the microscopic findings in the retina, choroid, and optic nerve of a case of acute disseminated lupus erythematosus in which the fundus lesions were observed clinically is sufficiently rare to warrant publication.

As Klauder and De Long¹ point out, lupus erythematosus is an exceedingly rare, chronic, less commonly acute, inflammatory disease of the skin. It is characterized by sharply margined, red or violaceous, variously sized patches. The lesions are found on the face much more commonly than elsewhere. These patches are followed by cicatricial atrophy.

The following clinical varieties have been described: (1) A circumscribed or discoid form; (2) a chronic variety; (3) a diffuse or disseminated variety which may be acute and terminate fatally; (4) a telangiectatic variety; (5) a nodular type.

In the great majority of cases the disease makes its appearance in the chronic discoid form. In this report we are concerned only with the rare Type 3, which is an acute or subacute, often recurrent, type marked at times by widely disseminated polymorphic lesions of the skin and mucous membranes, accompanied by constitutional symptoms. Frequently there is a widespread visceral involvement and a variable clinical picture. As Kierland² pointed out, the Senear-Usher and

the Libman-Sacks syndromes are related to this condition. Although some internists and dermatologists believe that the localized discoid type of lupus erythematosus is a different disease from acute disseminated lupus erythematosus, it is significant that in a third of a series of 30 cases of acute disseminated lupus, Montgomery³ found that the disease started as the chronic localized discoid type. The interest of internists in disseminated lupus erythematosus, according to Stickney,⁴ dates from a paper by Osler,⁵ in 1895, on the "erythema group" in which he emphasized the grave systemic manifestations of a group of cases, many of which were undoubtedly disseminated lupus erythematosus. Since the disease is entirely distinct from lupus vulgaris, and since a tuberculous etiology has not been proved, Rose and Pillsbury⁶ feel that it is unfortunate that the term "lupus" is part of the nomenclature of the disease.

GENERAL MANIFESTATIONS OF THE DISEASE

While the disease is rare, Ludy and Corson⁷ state that acute disseminated lupus erythematosus is rapidly increasing in frequency. The disease has been studied extensively by Stillians,⁸ Matthews,⁹ Rose and Pillsbury,⁶ Stickney,⁴ and others.

In addition to the skin lesions the symptoms are those of a prolonged low-grade fever which fluctuates irregularly.

The skin lesions may precede, accompany, or follow the visceral and systemic manifestations of the disease, or they may

[†] By invitation.

be entirely absent. As a rule they are polymorphic and active. The exposed surfaces of the body are the sites of predilection, although no cutaneous or mucous surface of the body is exempt. A wide variety of lesions may occur simultaneously or in succession such as urticarial, eczematoïd or erysipeloid areas, purpura, petechiae, purplish or reddish brown macules, bullae, telangiectasis, and ulcers. The most common lesion is the deeply erythematous, swollen patch or plaque of varying size. In acute disseminated lupus erythematosus, a puffy erythematous lesion may appear upon the face, and include a goodly portion of it. There may, for a time, be a sharp demarcation about the eyes and at the frontal hairline, but the eruption soon becomes disseminated and involves large portions of the extremities and trunk. Hemorrhagic, vesicular, and bullous lesions are numerous. When remissions occur, marked atrophy, scarring, or pigmentation may follow subsidence of the acute lesion. Deep subcutaneous abscesses are not infrequently observed. The lesions may resemble a number of cutaneous diseases, such as seborrheic dermatitis, dermatitis venenata, erythema multiforme, Boeck's sarcoid, erysipelas, pellagra, and others.

There is gross evidence of pathologic changes in the endocardium in 30 percent to 50 percent of the cases. The tricuspid and mitral valves are most frequently involved, and show nonbacterial vegetations on the endocardial surfaces. Even though the lesions occur chiefly in the endocardium and pericardium, electrocardiographic examination may show some damage to the myocardium. Acute lupus erythematosus may simulate bacterial endocarditis or acute rheumatic fever; however, the cultures are negative.

Renal involvement occurs in practically every case. The clinical picture may suggest glomerulonephritis, pyonephrosis or

nephrosis, "diffuse" or "interstitial" nephritis, or tubular nephrosis. Urinary findings are not consistently characteristic of any particular type of renal lesion. Baehr, Klemperer, and Schiffrin¹⁰ have described what they believe to be the characteristic renal lesion of the disease, and one which they report having seen in no other condition, with the possible exception of the kidney of eclampsia. This renal lesion consists of a peculiar hyaline thickening (wire loop) of the walls of the glomerular capillaries. These wire loops have been found to contain no amyloid or lipid material. Accompanying these changes they describe proliferative and thrombotic processes involving part or all of the glomerular vasculature; the picture may resemble that of the embolic glomerulonephritis seen in subacute bacterial endocarditis. Renal involvement has been considered the most common visceral manifestation. Renal insufficiency, however, does not play an important role in causing death, since, as Keith¹¹ points out, severe chronic uremia very seldom occurs.

Patients with this disease also show a leukopenia, anemia, loss of weight, and asthenia, followed by marasmus and cachexia. Stillians⁸ pointed out that the white-cell count may be at a low normal level, and that it fails to rise with elevation of the temperature. When positive blood cultures are obtained, Matthews⁹ feels they are the result of contamination, or are due to a terminal bacteremic invasion by organisms having no causal relationship to the disease.

Lymphadenopathy may be generalized or localized to the cervical region. Both the superficial and deep lymphatic chains may be affected. Enlargement is usually moderate but occasionally glands as large as a fist may be observed. Matthews⁹ found nothing characteristic about these glands in microscopic sections.

It is interesting that Matthews⁹ found the serologic tests for syphilis falsely positive in 17 percent of the cases. The sedimentation is also frequently found to be increased in rate.

Hepatomegalia has been reported as a common finding and is said to result from cloudy swelling, pylephlebitis, or abscess formation. Jaundice may occur but is rather infrequent. Splenomegalia occurs rather frequently but it rarely attains an extreme degree. The splenic enlargement, according to Matthews,⁹ is usually due to infarction. Rose and Pillsbury⁶ have demonstrated that the spleen may show parenchymatous degeneration, acute splenitis and perisplenitis, acute congestion, necrosis with arteriolar obliteration, abscess formation, and infarction.

In the gastrointestinal tract, embolic and thrombotic phenomena occur in the mesenteric circulation and this may result in a picture simulating acute abdominal emergencies and lead to unnecessary surgical exploration. Hematemesis and melena are frequent manifestations of ulcerating lesions in the mucosa of the stomach or intestines. Diarrhea is the commonest gastrointestinal symptom.

This disease also affects the lungs; in fact pulmonary involvement is among the chief causes of death. The lesions found clinically and at autopsy are variable and include pneumonia, abscess formation, gangrene, atelectasis, and infarction. Pleural effusions are common and may be serous, sanguineous, or purulent. Severe tracheolaryngitis has been seen occasionally.

The disease seems to have a predilection for the larger joints, and synovial effusions of a serous, sanguineous, or purulent character may occur. The joint symptoms may resemble those of fibrositis, rheumatic fever, and acute, subacute, or chronic infectious arthritis. Rose and

Pillsbury⁶ also point out that arthralgia may precede or accompany the eruption and systemic phases of the disease.

The mucous membranes may also be involved and ulcerative lesions may occur in the gastrointestinal tract, vagina, bladder, and pharynx, which give rise to alarming hemorrhages. Matthews⁹ reported gangrenous ulcerations in the mouth, tonsils, and pharynx.

As a result of central nervous-system involvement, convulsions may occur even in the absence of renal disease and uremia. The colloidal gold curve may be of the paretic type. Careful pathologic studies of the brain have revealed vascular changes in many instances.

The disease is found in all age groups, but women between puberty and the menopause are in the large majority. In Kierland's² cases, they were predominantly in the 20- to 30-years age group. He also found that 80 percent of the cases having the subacute and acute form of this disease occurred in women. These figures are in agreement with those of other observers.

ETIOLOGY

The etiology of acute disseminated lupus erythematosus is essentially unknown but several possible causative factors have been suggested. Inasmuch as there is a close association with tuberculosis in many of the chronic cases of lupus erythematosus, it has received a good deal of serious consideration as a causative factor. This association is not so evident in the acute form of the disease. According to Stillians,⁸ associated skin lesions of lupus erythematosus never give histologic evidence of tuberculosis. Other writers regard the disease as a manifestation of tuberculous infection or as an allergic response to tuberculo-toxin; this view appears to be based largely upon the following facts: (1) The oc-

casual occurrence of active tuberculous lesions in patients with the disease; (2) the alleged recovery of tubercle bacilli from the blood stream in some cases; and (3) the marked response which usually occurs after tuberculin inoculation. Slocumb¹² has stated that the incidence of tuberculosis in American patients with lupus erythematosus is no greater than that found in any other systemic disease. Bergmeister¹³ and Pilat,¹⁴ respectively, have classified the intraocular lesions as metastatic tubercles in the retina and as acute tuberculous choroiditis. In spite of the above facts and the implications suggested by its name, lupus erythematosus is no longer considered to be of tuberculous origin.

Another theory which has received consideration is that the disease is the result of a generalized toxic reaction similar to the Schwartzman phenomenon. According to Stillians,⁸ Brocq's theory that toxins from infectious foci of various kinds are responsible for the lesions of lupus erythematosus has long been the favorite among dermatologists.

The release of unknown toxic products elaborated in the skin by various physical agents has also been considered as the causative factor. The tendency for acute cutaneous and systemic manifestations to appear or recur after exposure to sun or ultraviolet light, roentgen rays, insect bites, cold, or the intracutaneous injection of irritating substances such as tuberculin has long been known.

Kiel¹⁵ has advanced what he terms the "vascular concept" of the disease. He assumes the presence of a theoretical toxin that has a selective affinity for the vascular system, chiefly the capillaries and to a lesser degree the venules and the arterioles. The action of this toxin produces proliferation of the vascular endothelium with subsequent formation of thrombic, perivascular hemorrhages and edema. These lesions are found in

every structure of the body but occur chiefly in the skin, joints, lymph nodes, bone marrow, lungs, heart, and spleen. Wagener,¹⁶ however, doubts that the type of retinopathy found in this disease is of vascular origin and feels there is a lack of histologic evidence to support the theory.

Stokes, Beerman, and Ingraham¹⁷ advance the hypothesis of an infection-allergy being the causative factor. They conclude that as the discoid type of lesion is expressive of local cutaneous infection-allergy of the follicular inflammatory type, so the acute disseminate type is the clinical type of lupus erythematosus with multiform disseminated cutaneous and systemic lesions resulting from allergic inflammation of the vascular system. The vasculo-allergic type then may be preponderantly local and cutaneous in its manifestations or preponderantly systemic. They admit that the clinical case for infection-allergy is not "massively pro, though there is also little con." As to the nature of the infection to which allergy develops or exists, they admitted that no absolute decision could be "had at this time."

DIAGNOSIS

The diagnosis of lupus erythematosus in the present state of our knowledge of the disease must depend chiefly, as Montgomery³ has pointed out, on the recognition of the cutaneous lesions. It is recognized, however, that acutely ill patients will be seen who present most, if not all, of the systemic signs and symptoms outlined above, but in whom no cutaneous lesions occur. The various manifestations of acute disseminated lupus erythematosus are not fully understood. All the clinical findings have not been satisfactorily correlated and so the diagnosis is frequently subject to some question. In the differential diagnosis of acute disseminated lupus erythematosus

several conditions must be considered. In *chronic discoid lupus erythematosus* the cutaneous lesions are similiar but there are no systemic manifestations of the disease. The chronic cutaneous lesions are typified by small, scaly, atrophic patches of pigmented skin on the face. If the skin lesions become more or less confluent and widespread over the body, and there is an absence of systemic manifestations, the condition is called *chronic disseminated lupus erythematosus*. Cases of chronic lupus, either the discoid or the disseminated type, according to Klauder and Ellis,²⁴ may develop into the acute disseminated form with fatal termination.

The ophthalmoscopic picture seen in Koch and McGuire's case¹⁹ was similiar to that which is seen in periarteritis nodosa and less typically in dermatomyositis. Positive blood cultures are sometimes found in the terminal stages but, as Matthews⁹ points out, it should be emphasized that a terminal bacteremia is not uncommon in disseminated lupus and this should not be interpreted as evidence of subacute bacterial endocarditis. The so-called Libman-Sacks syndrome is at times accompanied by skin lesions identical to those of acute disseminated lupus erythematosus. It seems beyond doubt that those cases described by Libman and Sacks with erythematous facial lesions were examples of acute disseminated lupus erythematosus. Rose and Pillsbury⁶ feel that whether their other cases represent instances of the same disease without erythematous skin lesions must remain uncertain for the present. Thrombocytopenic purpura may precede, accompany, or follow the syndrome of acute erythematous lupus.

COURSE OF THE DISEASE

The clinical course of the acute form of this disease is exceedingly variable. Acute exacerbations and remissions typify the disease. The acute form is usually

fatal in from two months to four years. The onset may be abrupt and the course short and stormy with fatal termination in 6 to 8 weeks, while other cases may be characterized by mild systemic reactions and prolonged remissions during which all cutaneous and visceral manifestations disappear. The course may be dramatically unexpected. According to Rose and Pillsbury,⁶ a moribund patient may occasionally recover or an extremely mild case suddenly become fulminating and rapidly fatal within a few weeks. Renal failure, bronchopneumonia, toxemia, or terminal bacteremia have been reported as the commonest causes of death. Stillians⁸ points out that during the course of the chronic forms of the disease (chronic discoid and chronic disseminated types) fever, albuminuria, bone and joint pains, and malaise are warnings of the onset of an acute exacerbation. The chronic discoid type only rarely exhibits rapid extension or acute visceral dissemination.

THERAPY

Treatment is purely supportive. Many drugs and varieties of therapy have been tried and found to be of little or no avail. In view of the fact that acute dissemination may occur following exposure to sunlight, ultraviolet radiation, X-ray therapy, trauma from irritating and stimulating local applications, all of these procedures had best be avoided. Gold and tuberculin are said to be dangerous in the treatment of this condition. Matthews⁹ has pointed out that it is perhaps better to know what not to do than it is to try a therapeutic regime blindly. Early recognition of the disease and the avoidance of certain dangerous procedures, especially exposure to sun and ultraviolet light, may prevent serious or even fatal exacerbations. O'Leary²⁰ warns that vaccines and serums provoke more unfavorable reactions than do drugs.

GENERAL PATHOLOGY

Mallory²¹ has stated that it is not always possible for the pathologist to make a final diagnosis even in a patient with typical clinical manifestations. Characteristic vascular lesions have been described by Baehr, Klemperer, and Schiffrin¹⁰ as consisting of (a) capillary dilatation with extravasation of blood and serum; (b) proliferative endothelial vascular lesions with thrombus formation; (c) degenerative or necrotizing lesions in the walls of capillaries, arterioles, and venules, often with hemorrhage into adjacent tissues. All three processes may be found in the same case and in any part of the vascular tree. Hyaline capillary thrombi are characteristic and wide-spread according to Rose and Pillsbury.⁶ Montgomery³ feels that the pathologic changes noted in the various internal organs are "essentially that of a toxic process, and except possibly for certain vegetative changes in the valves of the heart as described by Gross in Libman-Sacks syndrome and the so-called wire-loop lesions in the capillaries of the kidney, the pathologic changes in the various internal organs are not specific or diagnostic for lupus erythematosus."

FUNDUS CHANGES

Fuchs²² has stated that various intraocular changes have been described in cases of acute lupus erythematosus. These include papillitis with irregular white circumscribed areas along the retinal veins, acute or healed areas of disseminated choroiditis, and macular involvement with retinal hemorrhages. For the most part the ocular lesions described in the literature have been limited to the retina and choroid, with a number of instances of optic-nerve involvement. There have been wide discrepancies in previous reports as to the types of lesions found in the various ocular structures.

In those cases where the retina showed involvement, the presence of some form of exudate or hemorrhage was regularly found. Prominently mentioned throughout the literature were cotton-wool patches, although in most instances the authors did not refer to them by that term. Such cotton-wool-like exudates were variously described as: fluffy exudates,^{10, 23} soft fluffy exudates,¹⁵ or cloudlike patches.²⁴ Frequently small exudates were referred to as: small white dots in the macular region,¹³ small light-colored spots in the macula,²⁵ small white lesions lying over the retinal vessels in the macular area,²⁶ small irregular yellowish-white elevated spots,²³ or small, round, white, elevated lesions situated underneath a retinal vein.²⁷

Similarly there was no uniformity in the character of the described hemorrhages. More often than not the hemorrhages were small and frequently were located in the macular area,^{19, 23, 24, 26} or near the disc.²³ However, larger hemorrhages were also seen, and Koch and McGuire¹⁹ noted a subhyaloid hemorrhage. Maumenee²³ stated that the distribution of the hemorrhages was not in relation to the white patches, nor to the larger retinal vessels. This finding was consistent with Koch and McGuire's¹⁹ opinion that the hemorrhages were located in relatively avascular areas of the retina, but were, however, in close proximity to the capillaries and to the smaller venules and arterioles, especially the former. Other authors, nevertheless, described them as being perivascular.^{6, 10, 15}

A less consistent finding was retinal vascular disease. Some of the vascular changes listed were: hyperemia of the retinal vessels,²³ sclerosis,²⁴ perivasculitis of the arteries,²⁸ marked periphlebitis and segmented periphlebitis,¹⁹ and areas of complete replacement fibrosis of veins and arterioles.¹⁹

Optic-nerve involvement was sometimes seen, although usually in a late stage of the disease. Ophthalmoscopically the following optic-nerve lesions were described: hyperemia of the optic nerve,¹³ blurring of the disc margins,^{23, 25, 27} papilledema,^{6, 23} primary optic atrophy,^{19, 28} and postneuritic optic atrophy.²⁹ In addition, circumpapillary edema^{10, 19} was seen.

Areas of retinal atrophy were mentioned,^{6, 28} and two authors reported retinal detachment.^{6, 9} Retinal⁶ and subretinal⁹ edema were occasionally present. Pillat¹⁴ found healed tuberculous choroiditic lesions in 16 cases of the chronic form. Three of these cases developed into the acute form, and, of these, two developed "indistinct, slightly elevated, grayish-white or yellowish foci of choroiditis in the posterior part of the fundi." Maumenee²³ found miliary tubercles in one case and choroidal degeneration was observed in one case by Rose and Pillsbury.⁶ Koch and McGuire¹⁹ described superficial choroidal, roundish, gray-white exudates and some they believed to be at the level of the choriocapillaris.

Pathologic studies of the eyes in acute disseminated lupus erythematosus are met with only rarely in the literature. Maumenee²³ studied five cases histologically. In all five cases he found cytoïd bodies in the retina which corresponded to the yellowish-white to white spots seen in the fundi. In addition, two of his specimens showed papilledema and two showed small hemorrhages in the nerve-fiber layer of the retina. In individual instances he found hyaline degeneration of the intima of the arteries typical of arteriosclerosis; hyaline degeneration of the intima of the choroidal vessels; serous exudate in the choroid and hemorrhages in the stroma of the choroid. In all five cases he found round-cell infiltration of the cho-

roid as did Semon and Wolff²⁷ in one case. The latter authors also found partially organized subretinal exudates of inflammatory cells. Goldstein and Wexler²⁸ described a case with optic atrophy in which they found marked degeneration of the media of the retinal arteries, and areas of retinal atrophy showing replacement fibrosis. Kurz,²⁶ like Maumenee, found cytoïd bodies in the nerve-fiber layer. These corresponded in position to the small white lesions which he had seen, ophthalmoscopically, to lie over the retinal vessels in the macular area. He refers to these cytoïd bodies as being in the nature of a varicose hypertrophy or ganglioform degeneration of the nerve fibers. Proliferative endothelial vascular lesions with thrombus formation have not been mentioned in any of the eye reports of this disease. It seems strange that if these vascular changes are a characteristic finding in lupus erythematosus that they do not appear in the retinal vessels.

CASE REPORT

Mrs. L. T., aged 30 years, was admitted to the University of California Hospital in the Department of Medicine under the care of Dr. William J. Kerr on November 19, 1941. The following data have been obtained from his records.

History. The patient had been in good health until September, 1940, when she complained of generalized headaches and lower abdominal pain appearing at the time of her menstrual periods. Two months later the lower abdominal pain became constant and was associated with burning on urination. She presented herself for examination by her family physician who, it is said, found albumin and cells in her urine and that her blood pressure was 140 mm. Hg. She was informed that she was suffering from nephritis and was put on a dietary regime. In the following months she became weaker, complaining of costovertebral angle pain, generalized muscular pains, and continued burning on urination. In April, 1941, she developed a severe laryngitis and a "lump" in the left side of her neck associated with fever. There were periods of troublesome palpitation, occurring two or three times daily lasting from 5 to 20 minutes. She had no dyspnea with these attacks.

Four months before admission she developed severe dizzy spells which were unrelated to po-

Fig. 1 (Cordes and Aiken). Fundus drawing 5 to 6 months before death, showing questionable or mild edema of nasal margin of the disc, cotton-wool patches, hemorrhages, and vascular changes.

Fig. 2 (Cordes and Aiken). Fundus drawing one month before death, showing edema of the disc, small edema exudates, advanced vascular changes, and evidences of thrombosis of small venous branches.

sition or activity. These dizzy spells usually lasted from 30 to 60 minutes and were associated with nausea. Two months before admission she developed what was called a "staphylococcus enteritis" during which time she vomited and passed numerous diarrheal tarry stools. For 2 or 3 months preceding admission, she ran a daily low-grade fever of around 100°F. On several occasions she developed showers of petechial hemorrhages over her body. She continued to lose weight and strength and when admitted was acutely and critically ill; the temperature was 38.7°C.; pulse 125; blood pressure 180/110 mm. Hg in the right arm, recumbent.

Physical examination. The essential features of the physical examination were moderate dehydration; erythematous macular rash over the cheeks, nose, and chest; evidences of mitral and aortic valvular heart disease; clubbing of the fingers; mild enlargement of the spleen, and a tender nodule, 1.0 cm. in diameter over the left forearm, 5 cm. below the elbow. The mucous membranes were uninvolued.

Laboratory tests showed mild anemia, 3,840,000 R.B.C.; evidences of kidney damage; four negative blood cultures. Spinal fluid colloidal gold, 0000000000; globulin, normal; cell count, 2 W.B.C. and 49 R.B.C.

Course of illness. The patient's general course while in the hospital was one of progressive decline with occasional waves of slight improvement. The blood pressure was generally high but on one occasion was as low as 145/95 mm. Hg, and on another occasion was as high as 210/160 mm. Hg. A low-grade septic type of fever persisted. Substernal and epigastric distress developed. A pericardial friction rub was heard. In addition a pleural friction rub was heard in the left lower axillary region, and pleural fluid was found to be present. The temperature rose steadily, she became comatose, the basis of which was assumed to be a diffuse cerebral vascular lesion. The patient died on June 14, 1942, 20 months after the onset of the disease. Clinical diagnosis at the time of death was acute disseminated lupus erythematosus with Libman-Sacks endocarditis.

Ophthalmoscopic examination. During the six months' hospitalization

period the eyes were examined ophthalmoscopically at intervals. There was variable but generally progressive reduction in visual acuity of both eyes. Visual disturbance was most marked and appeared first in the left eye. In the beginning there was questionable or no edema of the discs. Later, edema of the discs was present and persisted to the end. A number of retinal cotton-wool or cotton-wool-like patches (fig. 1) were seen on first examination and were present to greater or lesser amount throughout the period

relatively normal while in others there were marked irregular localized narrowings, even to the point of complete occlusion. Associated with these narrowings was a varying degree of perivascular thickening. Evidences of arteriosclerosis were also present. Toward the end the discs began to show pallor.

AUTOPSY FINDINGS

General pathologic report (résumé). Mitral and aortic valvulitis; abacterial verrucose vege-

Fig. 3 (Cordes and Aiken). (H&E low power) Retina. There is thrombosis of one retinal arteriole in the section. Also two other retinal arterioles show marked intimal thickening with occlusion of the lumen.

of observation. Retinal hemorrhages were for the most part small and irregular in shape; some were situated in the deeper layers of the retina; others showed striations and were flame-shaped, indicating their location as being in the nerve-fiber layer.

As the edema of the discs increased, it extended a greater distance out into the retina, especially into the macular area where small, irregularly round, white exudates were present (fig. 2). No definite stellate figure developed during the course of the disease.

The most interesting and striking features in the fundi were the vascular changes. The veins were mildly dilated and showed considerable irregularity in caliber. In a number of places they showed perivascular thickening. A shower of hemorrhages was seen along the distribution of several of the small venous branches, indicating the thrombotic nature of the vascular lesions. The spotty and disseminated distribution of the changes in the retinal arterioles was most interesting. In some areas the arterioles appeared

tations; cardiac hypertrophy. Multiple emboli in the brain stem with areas of focal necrosis involving the inferior portion of the pyramidal decussation. Multiple embolic pulmonary infarcts. Thrombosis of the right auricular appendages. Bilateral bronchopneumonia. Kidneys showed arteriosclerosis and multiple areas of focal glomerulonephritis. There was arteriosclerosis of the heart, spleen, and brain; atherosclerosis of the aorta. Marked central congestion of the liver. Lupus with involvement of the skin of the face and trunk. Right knee showed chronic synovitis.

Eye pathology. (Dr. Michael J. Hogan) *Gross examination.* The specimen consisted of the posterior half of the left eye which was removed at autopsy. Along some of the vessels, which showed white perivascular sheathing, were large, round retinal hemorrhages and a few dense, small round, white exudates. With the dissecting microscope, widespread patchy perivascular sheathing was visible.

Microscopic examination. Retina. Postmortem

changes were fairly marked in all layers, but especially so in the ganglion cell layer, nerve-fiber layer, and in the rod and cone processes. Some of the arterioles showed thrombi, without changes in the structure of the walls and these

exudates were found in the outer nuclear layer as well.

Surrounding most of the retinal vessels were fairly broad areas of degeneration (possibly postmortem). These degenerative areas were

Fig. 4 (Cordes and Aiken). (H&E high power) Retina, showing extensive deposition of the hyaline-like exudate in the outer retinal layers.

times thrombosed. Other vessels showed sub-intimal thickening, with narrowing of the lumen. The veins did not seem to show much involvement. There was no inflammatory infiltration into the retina.

Choroid. The small arteries and arterioles of the choroid showed widespread changes, which were similar to those seen in the retinal arterioles (fig. 7). Some of these vessels showed marked subintimal thickening, and the lumina

were reduced the diameter of 1 or 2 red blood cells, or were completely occluded (figs. 8, 9, 10). Other small arteries contained thrombi without evident disease of the wall. Still others showed marked hyalinization of the walls, with

edema, with crowding of the retinal nuclear layers away from its edge. There was patchy atrophy, with demyelination of many nerve-fiber bundles. Surrounding, and posterior to the entrance of the central vessels into the nerve, the

anterior to the entrance of the vessels. In this degenerated area many of the small vessels were occluded by thrombi, and had thickened walls. More anteriorly the central artery showed intimal thickening.

COMMENTS

From an analysis of the fundus findings in the literature and from our own observations, we are not inclined to re-

gard any single fundus lesion, or combination of fundus lesions, as being pathognomonic of lupus erythematosus. It is possible, however, to arrive at several general conclusions. When the disease becomes systemic, the initial fundus changes may be limited to dilatation of the retinal vessels. At this time, or soon thereafter, cotton-wool exudates and possibly hemorrhages may appear. This so-called "toxic retinitis" is probably the most typical and frequent fundus finding encountered in lupus erythematosus. This conclusion is consistent with the opinions of Wagener¹⁶ and others.

It is our belief that fundus changes beyond this stage are to be regarded as secondary to involvement of certain of the visceral organs, especially the kidneys and heart, and are due to widespread involvement of the arterial vascular system. This case did not come under our observation until 14 months after the onset of the disease. By that time the patient had already developed a hypertension and showed evidences of kidney damage and valvular heart disease. At this stage the retinal arterioles showed widespread organic changes in addition to cotton-wool exudates and hemorrhages, and it is not at all unlikely that these changes were nothing more than the manifestations of a diffuse hypertensive arteriosclerosis. Microscopic examination of the retina and the visceral organs tend to substantiate this conclusion. The vascular changes which were seen in this case, such as intimal thickening and sclerosis of the arteriolar and arterial walls, with narrowing and occlusion of their lumina, are characteristic of hypertension. Sections taken from the retina and visceral organs were sent to Dr. Henry P. Wagener of the Mayo Clinic, and he and Dr. J. W. Kernohan concurred in the opinion that the changes were characteristic of hypertensive-arteriolosclerosis. Dr. Kernohan

was unable to find any evidence of the type of vascular lesion presumed to be characteristic of the vessels in lupus erythematosus in the retina, the kidney, or any of the other tissues. He was especially interested in the thromboses, particularly in the retinal vessels, but stated he could not diagnose them as being of lupus origin since the typical intimal endothelial changes were absent. He further believed that the retinal and renal lesions represented a diffuse arteriolosclerosis complicating the lupus, rather than an actual lupus lesion of the vessels and kidneys with secondary hypertension.

It would seem, however, that the widespread vascular occlusive lesions would fit reasonably well into the picture of lupus. These may be embolic in nature, or due to thromboses occurring at the site of a toxically damaged endothelium. The patchiness of the vascular lesions observed clinically was confirmed pathologically. Some of the retinal arterioles appeared reasonably normal while others showed hyperplastic sclerosis, narrowing of the lumina and thromboses. This thrombotic and patchy nature of the vascular lesions is not inconsistent with lupus, although this point must be left open to question.

Wagener¹⁶ recently made the statement that "in view of the rather frequent occurrence of vegetative endocarditis in cases of acute disseminated lupus erythematosus, it is rather surprising that embolic phenomena are not observed more often in the retina." He reported such a case in which he observed an area of ischemic edema in one retina associated with closure, probably embolic, of a small terminal arteriole and, a few days before death, a number of petechial hemorrhages, with white centers, in each retina. The absence of petechial retinal hemorrhages in our patient is certainly surprising considering the fact that showers of

such hemorrhages were seen in the skin, and that at autopsy multiple emboli were observed in several of the organs, particularly the brain and lungs.

SUMMARY

A case of acute disseminated lupus erythematosus in a 30-year-old woman was observed clinically for a period of six months before fatal termination.

Fundus examination revealed cotton-wool exudates with small irregular hemorrhages as well as flame-shaped hemorrhages. There was edema of the disc. The most striking features were the vascular changes. The veins were dilated and irregular in caliber, with perivascular thickening and small isolated venous branch thromboses. The arterioles showed a spotty and disseminated distribution of markedly irregular localized narrowings. In some areas there was complete occlu-

sion, associated with perivascular thickening. There was also arteriolosclerosis.

Microscopic examination of the eye showed, in addition to the hemorrhage and exudates, subintimal thickening and sclerosis of the arteriolar and arterial walls with a narrowing of the lumina. There were scattered, widespread vascular occlusive lesions present. The vessels did not, however, show the intimal endothelial changes usually considered as characteristic of acute disseminated lupus erythematosus.

From a review of the literature and our own observations, we are not inclined to regard any single lesion or combination of lesions pathognomonic of lupus erythematosus. The so-called "toxic retinitis" is probably the most typical and frequent fundus picture seen in acute disseminated lupus erythematosus.

CAPILLARY FRAGILITY AND CAPILLARY PERMEABILITY IN RELATION TO RETINAL HEMORRHAGE*

RALPH L. SHANNO, M.D., J. Q. GRIFFITH, JR., M.D.,[†] AND
WILLIAM O. LAMOTTE, JR., M.D.
Philadelphia, Pennsylvania

The pathogenesis of retinal hemorrhage is frequently obscure. There is at least a possibility that certain of the cases may be due to an alteration in the capillary wall which may be present throughout the body, although obvious lesions may appear only in the retina. In an attempt to explore this possibility we have carried out certain tests, especially tests intended to demonstrate increase in capillary fragility and permeability in the cutaneous capillaries, in a series of patients suffering from retinal hemorrhage. Increase in capillary fragility would be expected to cause hemorrhage primarily in vessels of capillary type. The retinal capillaries would probably share in any capillary change occurring generally.

Since the drug rutin has been shown to improve capillary fragility when tested in the cutaneous capillaries,^{1, 2} and also more recently³ to have a beneficial effect on increased capillary permeability, a clinical study of its effect on the recurrence of retinal hemorrhage was undertaken.

MATERIAL AND METHODS

Two separate groups of patients were studied. One group consisted of 47 subjects with recent retinal hemorrhage who were referred from other dispensaries of the University Hospital to a special dis-

pensary set up for this study. This group will be subsequently referred to as the dispensary group or dispensary series. Each patient was requested to visit the dispensary at least once every six weeks. In some cases visits were more frequent and in other cases, due to faulty patient coöperation, they were farther apart. However, 37 of this group returned for from 1 to 14 follow-up studies. All patients in this group were examined ophthalmoscopically on each visit by one of us (LaM.) with careful charting so that it seems reasonably certain that all ophthalmoscopically visible hemorrhages were detected.

The second group consisted of 32 patients with retinal hemorrhage referred as private patients to one of us (J.Q.G.). This group does not include all the patients referred to (J.Q.G.) because of retinal hemorrhage, but only those referred by nine ophthalmologists who, because of association with the authors or previous experience or interest in this study, might be expected to supply accurate data and coöperation in the follow-up study. Fifteen patients in this group were followed for a period up to four years, usually every 2 or 3 months so far as the studies (by J.Q.G.) are concerned. Eyegrounds were reëxamined by the referring ophthalmologists but at more irregular intervals for this, the private group or private series, than for the dispensary group. In no case were these patients studied by the one (LaM.) who followed the eyegrounds of the dispensary group, nor in any case were the eyegrounds actually

*From the Robinette Foundation of the Medical Clinic and the Department of Ophthalmology of the Hospital of the University of Pennsylvania. This study was aided by a grant from Abbott Laboratories, North Chicago, Illinois.

[†] Atwater Kent Fellow in Medicine.

charted. Thus, for the private group, the occurrence of a small retinal hemorrhage, not apparent subjectively to the patient, nor noted by the ophthalmologist, nor absorbed before examination, cannot in every case be entirely excluded.

Blood pressure was measured routinely, and patients were questioned for known diabetes. Special studies included: (1) Measurement of capillary fragility based on the method of Göthlin³ but modified so that usually only the first stage was carried out. (2) Measurement of cutaneous lymphatic flow by the dye method of McMaster.⁴ (3) Measurement of plasma creatinine by the method of Steinitz and Turkand.⁵ (4) Determination of cutaneous capillary mobility by capillary microscopy.⁶ (5) In certain cases, bioassay for antidiuretic hormone of the pituitary gland.⁷

Studies 1 and 2 proved to be of considerable interest, and will be reported in detail. Studies 3, 4, and 5 proved to be relatively less important and will not be reported in detail, but simply considered in the discussion.

MEASUREMENT OF CAPILLARY FRAGILITY

1. A circular area, 6 cm. in diameter, is marked off in each antecubital space.

2. A blood-pressure cuff is placed about each upper arm and inflated to 35 mm. Hg for 15 minutes. Thereafter, petechiae are counted, using a good light and lens.

If 2, 1, or no petechiae appear, the fragility is considered normal; if 6 or more petechiae appear, the fragility is increased; if 3, 4, or 5 petechiae appear and the test is being carried out for the first time, fragility is borderline and a second stage, as described elsewhere,³ must be carried out; in a follow-up study, however, where the previous test was abnormal, 3, 4, or 5 petechiae are considered to indicate increased capillary fragility.

MEASUREMENTS OF CUTANEOUS LYMPHATIC FLOW

1. The blue colloidal dye, patent blue, is used, purified according to the method of McMaster.

2. About 0.04 cc. of the dye is injected intracutaneously, in the antecubital space, and the spread of streamers is followed for a period of 15 minutes. Spread during the first minute is due to the force of the injection, but thereafter spread depends upon the rate of lymph flow. If the spread from the 1st to the 15th minute is three-fourths of an inch or more, cutaneous lymphatic flow is increased; if less than three-fourths inch, flow is normal. The color disappears, always within two days, often in 18 hours. In some 5,000 tests, no reaction has occurred nor has any permanent discoloration resulted. Rarely, a transient redness is seen about the area of injection, lasting one hour.

The significance and importance of cutaneous lymphatic flow has been considered in more detail elsewhere,⁸ but it may be summarized here as follows: (a) Lymph is formed of fluid which has left the capillaries, and its rate of formation determines its speed of flow through the lymph vessels. (b) Increased rate of lymph flow can only result from increased passage of fluid through the capillary wall. (c) Increased passage of fluid through the capillary wall results when capillary pressure is increased without impediment to capillary flow, or where there is a primary increase in capillary permeability. In this sense, increased capillary pressure is thought to occur in association with fluid retention, in either renal or pituitary disease. If these conditions can be excluded, increased lymphatic flow may be presumed to be on the basis of increased capillary permeability, when it is frequently but not invariably associated with increased capillary fragility. This concept, however, as just described, has appeared

only about two years ago, so that lymphatic-flow studies are lacking in certain of the early cases of the private series.

PLAN FOR RUTIN MEDICATION

The nature and use of rutin has been described elsewhere.^{1, 2, 3} In general, the initial dose given was 60 mg. per day (20 mg. 3 times a day) and tests for capillary fragility and permeability, one or both depending on what findings were

subjects, capillary fragility was increased in 24 subjects but normal in 8; cutaneous lymphatic flow was increased in 8 subjects, normal in 15, and not done in 9; both tests were abnormal in 7 subjects and normal in 6 subjects.

Considering the two series as a whole, capillary fragility was increased in 47 of 79 subjects, or approximately 60 percent. Of the 70 subjects in whom cutaneous lymphatic flow was measured, it was

TABLE 1
RESULTS IN STUDIES OF CAPILLARY FRAGILITY AND CAPILLARY PERMEABILITY
IN RELATION TO RETINAL HEMORRHAGE

	Capillary Fragility			Lymphatic Flow			Both Tests	
	In-creased	Nor-mal	Total	In-creased	Nor-mal	Total	In-creased	Nor-mal
Dispensary group	23	24	47	25	22	47	12	11
Private group	24	8	32	8	15	23	7	6
Total	47	32	79	33	37	70	19	17

originally abnormal, were repeated in six weeks. The dose of rutin was increased so long as either test remained abnormal but was held constant when both tests were normal. The cases of the private series were studied every six weeks as long as either test was abnormal, and thereafter every three months, so far as possible. In general, patients in the dispensary group were seen every six weeks, regardless of the outcome of previous tests.

RESULTS

I. FINDINGS ON INITIAL EXAMINATION

1. *Capillary fragility and cutaneous lymphatic flow.* (See Table 1). In the dispensary group, consisting of 47 subjects, capillary fragility was increased in 23 subjects but normal in 24; cutaneous lymphatic flow was increased in 25 subjects but normal in 22; both tests were abnormal in 12 subjects and both tests were normal in 11 subjects.

In the private group, consisting of 32

found to be increased in 33 persons, or 47 percent. Putting it another way, in the 70 persons in whom both tests were carried out, only 17 subjects, or 24 percent, showed normal tests for both capillary fragility and cutaneous lymphatic flow.

2. *Sex incidence.* In the dispensary group, there were 19 males, and 28 females; in the private group 22 males and 10 females. Thus, in the combined groups there were 41 males and 38 females.

3. *Age incidence.* In the dispensary group the age range was from 29 to 72 years, but 85 percent of the patients were over 40 years of age, and 74 percent were aged 50 years or over. In the private group one patient was aged 22 years, 3 were between 31 and 40 years of age, 6 more were between 41 and 50 years, and the remainder, or 22 patients, were over 50 years of age, the oldest patient being aged 82 years.

4. *Incidence of diabetes.* In the dispensary group, 22 of the 47 patients were

diabetic, as were 5 of the 32 in the private group, making a total incidence of 27 out of 79 patients, or 34 percent.

5. *Incidence of hypertension.* In the dispensary group, 19 patients were hypertensive (systolic blood pressure 150 mm. Hg or more, or diastolic 100 mm. Hg or more, or both) and 15 of the private group, making an incidence of 34 out of 79 patients, or 42 percent.

6. *Incidence of diminished renal function as evidenced by elevation of plasma creatinine.* In the dispensary group 7 patients showed slight elevation of plasma creatinine, as did 4 of the private group, making an incidence of 11 out of 79 patients, or 14 percent.

II. RESULTS OF RUTIN THERAPY AND FOLLOW-UP STUDIES

1. *Period of follow-up study.* Patients in the dispensary group have been followed for 6 weeks to 13 months. Ten of the 47 patients failed to return, so only 37 are shown in Table 2. Only 15 of the private series have been followed, for a period of 6 to 51 months, averaging 13 months.

2. *Effect on capillary fragility.* Of the 37 patients followed in the dispensary group, 19 showed an initially increased capillary fragility. Of these, following rutin therapy with the dose and for the time interval as shown in Table 2, 9 showed fairly consistent return of test to normal, while in 10 fragility either remained consistently increased or was increased at times. It is not possible at this time to predict the result of increased rutin dosage or a longer interval of follow-up, especially as some of the patients are no longer under observation. Of the 15 patients followed in the private group, capillary fragility remained consistently increased in two and was intermittently increased in two, while in 11 it became normal.

3. *Effect on cutaneous lymphatic flow.* Of the 37 patients followed in the dispensary group, 22 showed an initially increased cutaneous lymphatic flow. Twelve of these showed a fairly consistent return to normal after rutin therapy, while in 10, lymphatic flow was either consistently increased or increased with sufficient frequency to make the course appear unsatisfactory. Again, one cannot predict the result of higher rutin dosage and a longer follow-up period. Of the 15 patients followed in the private group, 8 showed an initially increased cutaneous lymphatic flow. All of these have shown return to normal with one exception and that patient, a woman of 66 who has been followed for 15 months at approximately two-month intervals, had only one abnormal test in the series which preceded by three weeks her second and last retinal hemorrhage.

4. *Effect on recurrence of retinal hemorrhage.* In Table 2, each symbol means one study of a patient, 52 patients in all being charted. The symbol for the study made nearest the time of occurrence of a retinal hemorrhage is joined with either an *h* (dispensary) or *H* (private). In the column designated as "First Visit" all symbols are shown with either an *h* or *H*. Three patients, who had been given rutin prior to their referral to the dispensary, are listed in the "First Visit" column at their respective rutin dosages.

Six patients in the dispensary group that were followed had initially normal tests for both capillary fragility and cutaneous lymphatic flow, although three of these, at either the first or second follow-up showed one or both tests abnormal and in two instances this change occurred coincident with a fresh retinal hemorrhage. All three were then started on rutin. One patient, with initially normal studies, was seen once in follow-up, was normal at that time, and was not seen

TABLE 2

since. The remaining two patients (of the six) were taking rutin at the time they were first seen in the dispensary. This was continued for a time. On subsequent follow-up one patient showed a fresh retinal hemorrhage, and both tests were abnormal. His dose of rutin was increased. The last patient was normal on follow-up, his rutin was discontinued, and he has remained well since and his tests have remained normal.

Thus, all but one of the patients charted in Table 2 took rutin at least at some time. Those indicated as not taking rutin after the sixth month represent cases that lapsed treatment, at least temporarily.

In the dispensary group, 18 of the 37 patients had at least one retinal hemorrhage during the follow-up period, and in five cases the hemorrhage was sufficient to affect vision and be subjectively noted, while in the remainder it was recognized only by ophthalmoscopic examination. In the private group, three of the patients had recurrent hemorrhage, all sufficient to affect vision.

Since several patients had more than one hemorrhage, it is apparent from Table 2 that a total of 51 retinal hemorrhages occurred in 21 persons during the period of observation. In these, there was

an associated increased capillary fragility 32 times, increased cutaneous lymphatic flow 12 times and, on seven occasions, hemorrhage occurred when both tests were normal. As Table 2 shows, hemorrhage occurred three times in persons not taking rutin, at least at the time preceding the hemorrhage.

5. *Rutin dosage.* As shown in Table 2, dosage ranged from 60 mg. per day to about 400 mg. per day, but 90 percent of the subjects studied were given 180 mg. per day or less. Three subjects who were followed longer than 2½ years were started on hesperidin (which does not appear in the table) but changed over to rutin about that time. Hesperidin has a chemical formula much like rutin, and was used by us originally. As a rule, the crude preparation of hesperidin acted like rutin, but the refined preparation was much less active and the crude preparation varied in potency. When rutin, a chemically pure substance which was uniformly active, became available, it was substituted in all cases for hesperidin.

DISCUSSION OF RESULTS

The incidence of elevated plasma creatinine, hypertension, diminished capillary mobility (9 cases), and positive bioas-

EXPLANATION: Each symbol appearing alone or in combination with another symbol, represents one period of study.

g, G indicates increased capillary fragility.

l, L indicates increased capillary permeability (increased cutaneous lymphatic flow).

x, X indicates a period of study in a patient whose general course is favorable in that retinal hemorrhage has not recurred and that capillary fragility and permeability are normal with fair consistency.

o, O indicates a period of study in a patient whose general course is unfavorable in that, while tests for capillary fragility and permeability are normal at the time of that study, they are either not normal consistently or, some time during the course of the study, a retinal hemorrhage has occurred.

h, H in combination with any other symbol means that a retinal hemorrhage has occurred near the time of the study.

g, l, x, o, h indicate patients of the dispensary group.

G, L, X, O, H indicate patients of the private group.

It should be noted that a patient represented by x or X is always represented by the same symbol, whereas unsatisfactory cases may be represented, depending on the findings, by g, l, o, h or G, L, O, H. By definition of a satisfactory case, h or H cannot appear combined with x or X, after treatment has been begun. The number associated with a symbol or symbol group indicates the total similar tests for that period, but this cannot always be translated into total number of patients since, especially for the longer periods, the same patient may appear more than once.

say for antidiuretic hormone (8 cases) did not significantly influence the results of therapy, and have not been reported in detail. Some difference might appear, however, in a larger series, and it is a clinical impression that the occurrence of any of these factors makes chance for success with therapy a little less likely. The same can be said for diabetes, although here the evidence is suggestive, but not absolutely significant.

It is quite apparent, however, that there is no relation between the degree of elevation of systolic and diastolic blood pressure, in subjects with hypertension, and the incidence of retinal hemorrhage.

The relation of increased capillary fragility and increased cutaneous lymphatic flow with retinal hemorrhage is significant, both in the initial hemorrhage and in recurrence, although it is obvious that a direct relationship seems to exist for only a certain group of the cases. There are undoubtedly cases where retinal hemorrhage occurs entirely apart from any change in general capillary fragility and permeability.

However, the role of rutin in correcting this capillary condition and, perhaps, thereby avoiding further hemorrhage is less clear. Rutin has been less effective in correcting increased capillary fragility and permeability in the present series than in the series of hypertensives previously reported,³ and the dosage required has frequently been larger. Moreover, certain patients have had recurrence of retinal hemorrhage even while tests for capillary fragility and permeability have been normal, so that one must conclude that additional factors are present in these cases or, perhaps, the initial hemorrhage has somehow predisposed to recurrence. Also, it should be noted that results appear to be better in the private than in the dispensary group, which may be due to difference in economic status,

or difference in sex predominance (more males in the private group, more females in the dispensary group), or simply a difference in completeness of ophthalmoscopic charting in which case the difference would be apparent rather than real. Unfortunately, it has not been practicable to study an untreated group, but it seems probable, but not absolutely certain, that rutin in some cases has been useful in preventing further retinal hemorrhages.

SUMMARY AND CONCLUSIONS

1. A considerable number of patients with retinal hemorrhage have an associated generalized capillary abnormality, as shown by abnormal response to tests for capillary fragility and permeability carried out on the vessels of the skin. The present series showed about 75 percent of such incidence for either one or both tests, and this is considered significant since these tests are uniformly negative in perfectly normal individuals.

2. Recurrent retinal hemorrhage, occurring during the period of study, was usually but not invariably associated with either increased capillary fragility or permeability, as shown by the tests.

3. In the series studied, rutin therapy was followed by return of tests to normal in about half of the dispensary group and in about 70 percent of the private group and such subjects usually, but not invariably, failed to develop further retinal hemorrhage. Considering the number of cases, the period of follow-up, and the scatter of results, final conclusions cannot be drawn, but it is at least suggestive that rutin, in adequate dosage and given over a long enough period, may be of value in preventing further retinal hemorrhage in that group of patients where the initial hemorrhage was associated with a generalized capillary fault.

THE EFFECT OF VISUAL TRAINING ON EXISTING MYOPIA*

H. ROMMEL HILDRETH, M.D., WILLIAM H. MEINBERG, M.D., BENJAMIN MILDER, M.D., LAWRENCE T. POST, M.D., AND T. E. SANDERS, M.D.
Saint Louis, Missouri

This research was undertaken in an effort to determine the value of visual training as a means of improving the visual acuity in patients with myopia. During the past few years, ophthalmologists have often been questioned by the parents of myopic children and by myopic individuals relative to the possibility of improving their sight, or of overcoming their near-sightedness, so that they might no longer have to wear glasses to see well at a distance. These queries have become so frequent that it seemed incumbent upon ophthalmologists to try to evaluate such methods of training as are employed by many optometrists and a few ophthalmologists.

The first efforts to improve vision by means other than glasses that received wide public attention were those advocated by the late W. H. Bates, M.D., who caught the public notice by means of a book entitled *Perfect Sight Without Glasses*, published in 1920. This idea, so fascinating to the wearers of glasses and especially to those who were forced to use strong corrections, naturally had great appeal and his training program developed a considerable following. The fact that very few have been able to dispense with their glasses is sufficient evidence of the ineffectiveness of the method. The idea, however, was so attractive that it was seized upon and efforts made to find more satisfactory methods than the Bates training for accomplishing the same purpose.

Many different training techniques have been studied and are employed. Most of them, however, have a common background of thought that has been standardized to a considerable degree in some of

* From the Department of Ophthalmology, Washington University, and the Oscar Johnson Institute. Funds for this research were contributed by the American Optical Company, Aloe's Optical Company, and the Department of Ophthalmology, Washington University. Read at the 51st annual session of the American Academy of Ophthalmology and Otolaryngology, Chicago, Illinois, October, 1946.

the optometric schools of the United States. Variations in details are, of course, practiced by almost everyone who gives this type of training. For the purpose of this study a method that closely approaches the most frequently employed ideas was used and will be given in detail later in this article. Longer or shorter periods of training might have produced different results. Two of the most outstanding cases of improvement observed during this time were not treated in this group, but by a practitioner not engaged in this particular project.

Although visual training for myopia had been in use for a number of years by optometrists at the time of the inception of this program, there was no report found in the American ophthalmic literature of a series of cases of myopia in which such training had been done with careful ophthalmologic examinations. It is interesting that coincidental with our study a somewhat similar one was being carried out in Baltimore. A series of 103 patients has been reported by Alan Woods, M.D., in the *American Journal of Ophthalmology* for January, 1946. Their work differed in that the entire training program was controlled by an independent group of optometrists whose detailed technique was not reported, although ophthalmologists of the Wilmer Institute examined the cases before and after training.

EXPERIMENTAL PROCEDURE

There are obviously innumerable phases to the problem of exercises in myopia, so it seemed best to attempt only a small part of the study in order that one phase at least could be comprehensively investigated; hence, the limitation to the study of the possibility of improving vision of myopic patients by training. Other pertinent questions are: How long does improvement, if any, continue? In what types of myopia is the training most effective?

Does the treatment have any effect on the rate of increase in progressive myopia? What would be the effect on other refractive states, as hyperopia, astigmatism, an anisometropia? What is the mechanism by which improvement, if any, is brought about?

As the primary objective of the problem as outlined was the determination of the possibility of improvement of the visual acuity in the myopic patient, it was evident that the group of patients should be standardized as much as possible, eliminating variables and unfavorable conditions so as to obtain the maximum improvement in the myopic factor. Because of this, the following standards were decided on: (1) Age 10 to 30 years. (2) Range of myopia in the greatest meridian: $-0.50D.$ sph. to $-3.00D.$ sph. (3) Astigmatism of 1 diopter or less. (4) No anisometropia of more than 1 diopter. (5) Correctible visual acuity of at least 20/20 in each eye. (6) No abnormal heterophoria, fusional defects, or substandard accommodation. (7) No internal or external organic condition.

The actual investigation resolved itself into the following steps: (1) The preliminary ophthalmologic examination. (2) The optometric survey. (3) The actual visual training. (4) The final ophthalmologic survey. (5) The analysis of the results. (6) The interpretation of the results with any possible conclusions.

In order to study the subject as intelligently as possible, it seemed wise to utilize the services of optometrists who were giving this type of training and of ophthalmologists who had not used these methods. Accordingly a team was formed for this study composed of ophthalmologists, optometrists, and opticians. The following arrangement of the team was decided upon: For the actual training, J. R. Bockhorst, O.D.; for the preliminary and final ophthalmologic surveys, H. Rommel Hildreth, M.D., William H. Meinberg,

M.D., Benjamin Milder, M.D., and T. E. Sanders, M.D.; and as a consulting group, E. C. Ebeling, O.D., Lawrence T. Post, M.D., and J. L. Stevenson. A full-time technician, Mrs. Harriet Thursby, did the majority of the actual training under the direct supervision of an optometrist.

OPHTHALMOLOGIC EXAMINATION

The ophthalmologic examination was divided among several individuals, the conditions and the examiner remaining constant for all patients examined. On the first visit (T. E. S.) a short history was taken including familial tendencies toward myopia, the length of time that myopic correction had been worn, the date of the last change, and the frequency of change of correction as related to progression. A general external and ophthalmoscopic examination was then made. Finally, the uncorrected visual acuity at 20 feet was determined with a Snellen letter chart. If the vision was less than 20/100, a shorter distance with the 20/100 letters was used. It was thought that this line would be more accurate than the 20/200 letter when used as a "walk-up," as it interpolates between 20/100 and 20/200.

Obviously the accurate determination of the visual acuity is the essential of the whole program. Theoretically a chart that is variable with similar and unfamiliar characters, as the Landolt broken ring, is much more desirable as it eliminates memory and past experience. At the beginning of the series the Landolt ring was used along with the ordinary Snellen chart with constant illumination. Three different Snellen charts were used interchangeably to eliminate memory. It was found early that lack of correlation between the Landolt and the Snellen charts was so great that it was difficult to interpret the results satisfactorily. The results with the Snellen chart alone were consistent and satisfactory. These find-

ings were also consistent with those of the optometrist using a Projecto-Chart. On the first visit the optometric examination (J. R. B.) was also done, as it was considered necessary to do this before a cycloplegic was used. This procedure is given in detail later.

On the next visit (H. R. H.) homatropine (2 percent) was instilled at 10-minute intervals for five times. Following this, a retinoscopy and a static refraction were done. The residual accommodation was then measured. At the third visit (B. M. and W. R. M.) a postcycloplegic refraction was done and the ocular muscle balance examined, which included: (1) The near point of accommodation as measured with Prince's rule; (2) the near point of convergence; (3) the degree of fusion as found on the synoptophore; (4) the lateral and vertical muscle balance at 20 feet and 16 inches as determined with prism dissociation; and (5) the lateral and vertical fusional amplitudes as determined with rotary prisms.

Following this preliminary examination, the patient was then referred for visual training (J. R. B.) as outlined hereafter.

After completion of the visual training the above ophthalmologic examinations were repeated exactly. At this time the individual patients were questioned as to their ideas of the value of the training and their opinion as to any subjective improvement in vision.

OPTOMETRIC EXAMINATION ROUTINE

The optometrist giving the training submitted a very detailed report on the examination routine and training technique he used throughout the program. This is available in the files of the Oscar Johnson Institute for those desiring to refer to it. A brief outline of this routine is as follows:

Steps 1 and 2. Visual acuity at 20 feet without correction and with habitually worn glasses.

Steps 3 and 4. Near vision with and without glasses.

Step 5. Measurement of interpupillary distance.

Step 6. Ophthalmoscopic examination.

Step 7. Ophthalmometric measurements.

Steps 8 and 9. Phoria test at 20 feet and 16 inches with habitually worn glasses. A 6-degree prism was placed base up and the horizontal phoria measured by the Risley rotary prism.

Step 10. Static retinoscopy at 20 feet.

Step 11. Dynamic retinoscopy at 20 inches.

Step 12. Dynamic retinoscopy at 40 inches.

Step 13. Subjective refraction test at 20 feet.

Step 14. Horizontal phoria at 20 feet with correction found in Step 13.

Steps 15 and 16. Adduction and convergence at 20 feet.

Step 17. Abduction at 20 feet.

Step 18. Vertical phoria test at 20 feet.

Step 19. Horizontal phoria at 16 inches with correction found in Step 13.

Steps 20, 21, 22, and 23. Listed as monocular and binocular cross-cylinder tests at 16 inches. A cross-cylinder was placed before each eye and a gridlike target observed. Spherical lenses were changed until the vertical and horizontal lines on the grid appeared alike.

Steps 24 and 25. Positive and negative fusional reserve relative convergence at 16 inches.

Step 26. Vertical phoria at 16 inches.

Step 27. Amplitude of accommodation.

Steps 28 and 29. Positive and negative relative accommodative reserve.

The detailed report ends with the sentence, "The 29th step completes the tests used and provides the basis for diagnosis of the subject's functional visual problem."

TECHNIQUE OF VISUAL TRAINING

The procedure outlined here required the use of an Arneson Squint Corrector, a Keystone Tel-Eye Trainer with certain Keystone cards whose numbers are given later, and an American Optical Company Wells-Head. The technique was broken into 11 individual steps laid out for a training period of 24 days averaging about one hour per day.

First Sequence, Six Days of Training

Step 1. Subject was seated before the Arneson Squint Corrector approximately 20 inches from the instrument. The in-

strument was equipped with a large disc with a medium-sized fixation target that could be rotated clockwise and counterclockwise. The right eye was occluded with a patch. The instrument was started rotating clockwise with instructions to the subject to fixate constantly the medium-sized target as it moved in a circular fashion. While fixating the target, his attention was also directed to the referential background of the disc which consisted of a black, red, and blue "E." The disc was rotated for three minutes. After the three-minute period the instrument was reversed to a counterclockwise direction, the whole procedure being repeated for three minutes. The same procedure was repeated occluding the left eye. Total working time for each eye was six minutes.

Step 2. Subject was placed before the Tel-Eye Trainer. The instrument was set at infinity position on the graduated slide, using Rotor 4 giving a four-second flash. No lenses were used. Two sets of cards were used, different sets on alternate days. The sight of the right eye was blanked out by manual push-button control and the left eye only was permitted to view the card, BO1-EC1. There were numbers interspersed throughout the field of the picture and the subject was instructed to locate the numbers in sequence from 1 to 10. If the picture or numbers appeared blurred, no changes or alterations were made in the setting of the instrument. The subject was instructed to keep watching the card until the numbers began to clear. This training was continued for five minutes. For training of the right eye the instrument setting remained the same with the exception that the left eye was now blanked out and Card BO1-EC3 inserted. This card was the same as the first with the exception that the numbers were in different positions throughout the field. On alternate

days Cards AN18 and AN16 were used in the same manner. Instructions in procedure remained the same. Step 2 was all monocular training.

Step 3. Subject remained at the Tel-Eye Trainer. No lenses were used. Slide remained at infinity and Rotor 4 was used. Both eyes were uncovered and for five minutes the Card BU5 was used with the subject seeing a picture of a room with the right eye in black and white, the left eye viewing a solid red field with numbers scattered through the field from 1 to 7. Instructions were to fuse the two unlike backgrounds into a single picture with the subject locating the black numbers and attempting to maintain clearness. When blur was reported, the setting of the instrument remained the same with emphasis placed on the subject's concentration to clear the numbers in spite of blur. Card BU5 was removed and Card BU6 inserted. The subject now viewed the black and white background picture in front of the left eye with a solid red field in front of the right eye, with numbers interspersed in the background from 1 to 8. The same instructions were given to the subject in viewing this card as in Card BU5. The procedure covered five minutes. Step 3 was monocular training in binocularity. Total training time for Step 3 was 10 minutes.

Step 4. Subject remained at the Tel-Eye Trainer. The instrument was set to flash alternately using Rotor 3 (3-second flash). Cards BO1-EC2 and BO1-EC4 were used. These cards were the same as the cards noted in the second step with the exception that the numbers were scattered in new positions. Instructions to the subject were to clear the numbers and the picture alternately with each eye. The second series of cards used in Step 4 were the AN1 and AN3. The cards of series one and two were used on alternate days. The AN1 card was a yellow

background card with numbers arranged in a circle and a star figure in the center connecting the numbers. When the alternating flash was started, the subject located the number 1 with the right eye, the number 2 with the left eye, number 3 with the right eye, number 4 with the left eye, and so forth, until he had gone through 12 numbers. Procedure was repeated for five minutes. The AN3 card was a similar card with these exceptions; the background of the card was now white with considerably smaller numbers. In addition to locating the numbers alternately, the patient was instructed to see the numbers clearly. Step 4 was an alternating monocular training procedure.

The above four steps were repeated for six days. Beginning the seventh day Step 5 was started, all of the previous steps being discontinued.

Second Sequence, Six Days of Training

Step 5. Subject was placed before the Arneson Squint Corrector, disc approximately 20 inches from the subject. A vertical dissociating prism, 6 degrees base up, was placed before the right eye. A vertical displacing prism, 4 degrees base down, was placed before the left eye. The subject was instructed to see two targets constantly. The instrument was turned on, rotating clockwise, with instructions to concentrate attention on the top target for 10 to 15 turns, always being aware of the lower target. Attention was then directed to the lower target as the fixating target for 10 to 15 turns with instructions to the subject always to be aware of the upper target. The procedure was followed for five minutes. The change in the prism setting was as follows: a 4-degree prism, base down, was now placed before the right eyes and a 6-degree prism, base up, was placed before the left eye with the same instructions followed for five minutes in the viewing of the two targets.

Step 5 was a rotation exercise, monocularly, in binocularity.

Step 6. Subject was placed before the Tel-Eye Trainer. The instrument was set at infinity on the slide, using Rotor 2 (2-second flash). Both eyes were uncovered. Cards BU8 and BU7 were used in the slide holder. When viewing Card BU8, the subject had a black and white picture in front of the left eye and a red and blue background in front of the right eye with numbers scattered throughout the red and blue field from 1 to 8. The color arrangement of the picture in front of the right eye was that the top half was red, the lower half blue. When the light flashed on, the black and white picture and the red and blue backgrounds had to be fused into one. The numbers scattered in the red and blue fields had to be clear. Procedure was followed for five minutes. Then Card BU7 was inserted into the instrument, which card was exactly reversed as compared to Card BU8. The black and white picture appeared in front of the right eye, the red and blue background appeared in front of the left eye. Numbers ranged from 1 to 9 in the colored field. The same instructions to clear numbers were given for this card. Procedure was followed for five minutes. Step 6 was monocular training in binocularity.

Step 7. Subject remained before the Tel-Eye Trainer instrument. Slide remained set at infinity, using Rotor 8 which gave alternate flash followed by binocular flash. Cards placed in the instrument card holder were ST2, Series I. This series consisted of three cards that produced stereoscopic vision and had control marks located in this sequence: Control marks on Card 1 were set toward the left side; control marks on Card 2 were located centrally; and control marks on Card 3 were located to the right. The subject was instructed to see the pictures

clearly and to fuse the control marks into a perfect cross. Each card was left before the subject for a period of five minutes. On alternate days ST2, Series II, were used with the same instructions to the patient as covered in the Series I. Step 7 was training in stereoscopic development and binocular control.

Step 8. Subject remained seated before the Tel-Eye Trainer. Slide holder was moved into the 2.50 position. Light flash, using Rotor 7, was set to operate simultaneously before both eyes. Cards SST2 were placed in the card holder. The series used were the cards numbered 0115, 0118, and 0113. Each card was viewed for five minutes. Subject's instructions were to fuse the cards into a single clear picture with emphasis being placed on his ability to produce a perfect cross of the control marks which appeared first to the left, next to the center, and lastly to the right. Step 8 was training in near-point stereopsis and binocular control.

Third Sequence, 12 Days of Training

Step 9. After Steps 5, 6, 7, and 8 had been repeated for six days, a reexamination was made after which the third phase of the visual training was instituted. Step 9 was the repetition of Step 7.

Step 10. Repetition of Step 8.

Step 11. Part I. Subject was placed before the Wells-Head. Steady light was used. Cards were placed at four inches and an auxiliary pair of plus-10 lenses was put in the instrument. Rotary prisms were placed before the subject's eyes. This setting produced a stereoscopic effect. At the zero markings, the subject looked at Card E2 with instructions to see the object with clearness and a sense of depth. The subject received frequent rest periods by closing eyes for approximately five seconds at a time. The rotary prisms were turned base out two degrees at a time with the caution to the subject that

the card must remain clear and single. The strength of the rotary prisms was constantly increased in these 2-degree, base-out jumps until the subject could maintain single and clear vision through a total of 32 degrees, base out, 16 degrees over each eye. Training on this card was performed for five minutes. For five minutes Card C4 was placed before the patient. Rotary prisms were started at 0, again increased two degrees base out at a time until a total of 32 degrees prism base out was reached, 16 degrees over each eye, with the same instructions that the object must appear clear and single. Card 6CM was then inserted. Rotaries were placed at 0 and increased in 2-degree steps until a total of 32 degrees prism base out, 16 degrees over each eye, had been reached with the same instructions to the patient that the target must be clear and single. Total training time was 15 minutes.

Step 11. Part II. Subject was placed before the Wells-Head. A 6-degree prism, base in, was placed in the instrument. The target viewed first was a type approximately Jaeger 3. The target was set at the 16-inch mark on the reading rod. The instructions to the subject were that the print must remain clear and single at all times. Then plus lenses were introduced in $\frac{1}{4}$ -diopter steps with the instruction to the subject, as the lens was changed, that again the print must remain clear and single. At the first increase of plus in the $\frac{1}{4}$ -diopter steps that produced a very slight blur, the subject was told to attempt to sharpen the print. When it became impossible for the subject to improve vision with increase in plus, the 6-degree prism, base in, in the rotaries was reduced two degrees at a time until the prisms were back to 0. At this time alternate size types of print were used varying between the original Jaeger 3 down to Jaeger 1.

The above steps, 9, 10, and 11, were continued for 12 visits. Again the subject was examined. Only those patients that appeared to have the ability to accomplish any further results in the above handling were permitted to repeat for an additional 12 visits.

Steps 9, 10, and Part I of 11 were used in those cases that appeared to be a basic problem of faulty convergence ability.

Steps 9, 10, and Part II of 11 were used in those cases that appeared to be a basic problem of faulty accommodative faculty.

RESULTS

This study represents a series of 87 patients examined, but a number of others were refused because of obvious defects. Thirty-three cases were either rejected or incomplete so that 54 case records were available for study. The majority of these patients were obtained by referral from the private practices of a number of St. Louis ophthalmologists, but some were referred by interested local optometrists. The series was not larger because of the strict limitations listed above.

As expected, no change was noted in the external or ophthalmoscopic examination of any patient. In no case was there any significant difference in the cycloplegic refractions done before and after the period of visual training. There was no more than one diopter of residual accommodation under cycloplegia remaining in any instance.

There was no appreciable effect of the visual training on the near point of convergence, near point of accommodation, or the fusional ability. About 50 percent of the cases showed an increase in esophoria of at least five prism diopters, or a decrease in the exophoria of about the same amount. In almost one half of the cases there was an increase of at least 10 prism diopters in adduction (positive fusional amplitude). There was no apparent

relationship between the amount of the myopia and the effect of the visual training on the muscle balance. There seemed to be no relationship between the induced changes in the muscle balance and the final visual result.

As our patients had no, or only small amounts of, astigmatism and of anisometropia, the refractive error of the fellow eyes of all of our patients were quite similar. Because of this, the average spherical equivalent of each patient based on his homatropine refraction could easily be determined. On this basis we were able to divide our patients into three groups: Group 1, those patients with average myopic errors of one diopter or less; Group 2, those patients with average myopia from -1.25 sphere to -2.00 sphere; and Group 3, those with average errors from -2.25 sphere to -3.00 sphere. It was also noticed that rather than try to analyze changes in the vision of separate "eyes," it was much more satisfactory to tabulate the binocular vision, particularly as this is the actual useful vision of the patient. Table 1 shows the pre- and post-training acuities of all the 54 patients, each patient being represented by his spherical equivalent.

The problem of how to evaluate an actual change in visual acuity on an accurate quantitative basis is extremely difficult. The simplest method is merely the number of lines improvement as measured on the ordinary Snellen chart. This presupposes that the difference between each line is the same, which is obviously untrue. Another method, which Woods used in evaluating his results, determines any improvement in terms of percentage points. This is done by determining the difference in the percentages of visual efficiency of the pre- and posttraining visions, using the tables developed in industrial ophthalmology for evaluation of losses in visual efficiency following in-

jury. As Woods points out, this weighs the results in favor of the higher degrees of myopia, in as much as a case with improvement from 20/200 to 20/100, or one line, shows an increase of 28 percentage points in contrast to a case with improvement from 20/50 to 20/20, four lines, which totals 22 percentage points. Obviously, this is not valid either clinically or statistically.

After studying our cases, it was evident that the easiest method was a simple qualitative one. Thirty patients, or 55.5 percent, showed no change in the visual acuity following the course of visual training. No patient had a reduction in vision. Twelve patients, or 22.2 percent, showed a questionable improvement which consisted of a change of one line or less in acuity. It was thought that this improvement was meaningless as it was within the limits of error. This is especially true since the patients during the period of training did not wear their ordinary corrections, thus giving them experience in the judgment of blurred images. Twelve, or 22.2 per cent, of the patients showed definite improvement of vision. These results in relation to the three separate groups are shown in Table 2. Using the visual efficiency table given in Snell's *A Treatise on Medicolegal Ophthalmology*, the improvement in percentage of visual acuity was found to average 27 percent in the favorable cases.

Group 3, those with an average myopia of -2.25 sphere to -3.00 sphere, consisted of 22 patients. Of these only three, or 13.6 percent, showed any appreciable improvement. There were six with some change and 13 with no change. The three cases representing improvement changed from 15/100 to 20/70, 20/100 to 20/50, and 12/100 to 20/50. This represents an average improvement of 35.7 percentage points.

Group 2, consisting of patients with

average myopia from -1.25 sphere to -2.00 sphere, included 23 cases. No change was noted in 15 cases and questionable changes in four. Four, or 17.4 percent, showed real improvement averaging 18.7 percentage points. These included three with change from 20/70 to 20/40, and one with improvement from 20/50 to 20/30.

Group 1 consists of nine patients with a myopic error of one diopter or less. Two each showed no change and questionable improvement. Five, or 55 percent, of these patients with small errors showed definite improvement with an average improvement of only 12.1 percentage points. Two of these patients showed improvement from 20/30 to 20/20, these being the only ones with improvement to 20/20. Two showed change from 20/40 to 20/25 and one 20/70 to 20/40.

A late recheck of the visual acuity was possible in 11 of the 12 cases showing improvement, the interval between the posttraining acuity and the final acuity ranging from 15 months to 23 months. These results are found in Table 3. It will be noted that five (Nos. 2, 3, 4, 5, and 10) retained all of their improvement, while three (Nos. 1, 6, and 7 reverted to their pretraining acuity. Two (Nos. 8 and 11) retained a slight improvement, while only one (No. 9) lost vision over the pretraining acuity.

CONCLUSIONS

In the first place, we realized before undertaking this problem that, no matter what our results, they would probably be criticized by both proponents and opponents of this controversial subject. If our percentage of improvement was not high enough to please the proponents, it would be charged that our technique of training was inadequate, omitting a critical or essential step. On the other hand, those who doubt that visual acuity can be altered by

such training will say that the methods of taking the vision were at fault and that removing a person's glasses will improve his unaided vision within a period of weeks without training.

Although different techniques or a larger and more varied series of cases might alter our exact figures, we believe that study of these results shows that vision in certain myopic individuals can be improved by training. Even if we

group in each series is 27 percent.

As might be expected, the best results occurred in the cases of low myopia of one diopter and under (55 percent improvement). There is less defect to be overcome in these cases and the better initial vision would probably make training easier. Although the series is not large enough to give accurate figures, the results of Group 2 (17.4 percent improvement) and of Group 3 (13.6 percent

TABLE 3
LATE VISUAL ACUITIES

Group	Patient	Spherical Equivalent	Pre-training Acuity	Post-training Acuity	Interval Months	Final Acuity	Result
Group 1	1	-0.75	20/30+3	20/20-4	15	20/25-2	Unchanged
	2	-0.50	20/30	20/20	16	20/20-3	Retained Improvement
	3	-0.75	20/40-2	20/25-3	16	20/25-3	Retained Improvement
	4	-1.00	20/40+1	20/25-1	19	20/20-3	Retained Improvement
	5	-1.00	20/70	20/40-3	15	20/40+3	Retained Improvement
Group 2	6	-1.25	20/50+2	20/30+3	16	20/40-2	Unchanged
	7	-1.50	20/70+1	20/40+1	17	20/70+	Unchanged
	8	-2.00	20/70	20/40+3	16	20/50+3	Partially Improved
Group 3	9	-2.25	15/100	20/70-1	23	10/100	Worse
	10	-2.50	12/100	20/50-1	22	20/50+2	Retained Improvement
	11	-2.50	20/100	20/50-3	18	20/70+1	Partially Improved

ignore the figures of the whole group showing improvement in 22.2 percent of our patients averaging 27.1 percentage points, this contention can be proved by the results in individual patients.

It is surprising how closely these figures compare with those of Woods. His favorable group, consisting of those patients showing a consistent improvement of each eye of at least 10 points, makes up 29 percent of his entire series compared to our figure of 22.2 percent showing definite improvement. It is interesting that the average improvement of the favorable

improvement) are quite similar. As Woods was unable to divide his cases on a basis of amount of myopia, these results cannot be compared.

On first study there seemed to be little direct evidence from our results as to the exact mechanism of the visual improvement. It is apparent that there is no change in the amount of the refractive error. There is also no indication of significant change in the ocular neuromuscular mechanism, such as might give rise by relaxation of the lens to a "negative accommodation." The impression gained

from these patients was that much of the improvement occurred at the cerebral level rather than in the retina. Although there was no method for absolute evaluation, it seemed evident that the most visual improvement occurred in those patients who were most intent in their training, putting into it more actual effort and concentration, and vice versa. It also seems

pretraining acuity seemed to get the best results.

Recently Pincus has reported observations of 50,000 examinations on eyes free of organic defects and correctable to 20/20. He correlated the unaided visual acuities with the refractive errors, including myopia, hyperopia, and astigmatism, in amounts up to six diopters. All of our

Chart 1 (Hildreth, Meinberg, *et al.*). Results obtained in visual training of existing myopia.

significant that many of the patients whose visual acuity did not change, thought that they could see better after the training. Also the subjective impression of improvement in the majority of the patients was out of proportion to the measurable change. Many stated that they thought they could "use" their eyes better.

One of us (B. M.) in analyzing the results made a significant observation that may well explain the benefit of training and may give the refractionist a criterion for selection of cases for training. It was noted that the patients with subnormal

cases were grouped according to their spherical equivalent and their pretraining acuity. Using the Pincus figures as a norm, it was found that in the 11 patients with an acuity of less than expected for their refractive errors, 8 of these cases (73 percent) showed some improvement. In the 43 patients having an acuity better than expected only 16, or 37 percent, showed improvement. This is expressed graphically in Chart 1.

Realizing that our series was somewhat small, the same one of us subjected Woods' series of cases to a similar analy-

sis, using only those cases that fulfilled our limitations. Since Woods did not report binocular vision, the analysis was done on individual eyes, 110 being available. In the group with pretraining vision worse than the norm, the percentage of improvement was 76.4 percent, while in the group with better vision than the norm, improvement was 38.8 percent. This again shows the remarkable similarity between our results and those of Woods. This also definitely confirms these observations.

Since the great preponderance of improved patients were those whose acuity was not as good as was to have been expected for the amount of their myopia, we may conclude that in these there had been a failure to utilize their visual possibilities to the best advantage and that training had improved the neurologic reception of the images. Better vision is not obtained by changing the anatomy, which remains stable, but by stimulating the visual effort and by improving the interpretation of the images seen.

It is probable that similar training would, in like manner, benefit some hyperopic patients.

The results of the late reexamination, about 1½ years after training, also may have significance. This showed that approximately one half of the patients retained their visual improvement, while only one patient showed worse than pretraining acuity. This would indicate that, at least in a small number of patients, the effect is not transitory. Although the number of patients is very small, these results suggest that an investigation of the possible relationship of visual training to the progression of myopia is indicated. This is without doubt the most important problem in myopia at present and is much more urgent than that of the improvement of visual acuity. Obviously, this question could be definitely answered only after a

carefully controlled study over a period of years.

We must conclude that visual training has a definite, but limited, value in about a fourth of selected myopic patients and none in the remainder. Good effects are preponderantly in those whose vision is less than expected for their known myopia. Considering the time and effort expended by the patient, the results, both in percentage of patients improved and in the actual amount of improvement per patient, must be definitely increased if the procedure is to be generally applicable to the routine management of myopia. It would seem desirable that some efforts be made to increase the effectiveness of the present methods of visual training.

In conclusion we believe that visual training merits further study from the ophthalmologist, particularly in relation to progression in myopia. This should not be left solely to the optometrist and to the psychologist as has been almost the case in the past.

SUMMARY

1. In an attempt to improve the visual acuity, a series of 54 selected cases of myopia was given a course of visual training which was preceded and followed by a complete ophthalmologic examination.

2. The technique of training, which was based on standard accepted procedures in this field, was given by an optometrist while the pre- and posttraining examinations were made by a group of ophthalmologists.

3. Thirty, or 55.5 percent, of the cases showed no change in their acuity, while 12, or 22.2 percent, showed a definite improvement, the best results being obtained in the cases with small amounts of myopia. Twelve patients, that is 22.2 percent, showed a change so slight as to be excluded in the results. The change in the improved group averaged 27 percent.

Eleven of the 12 improved patients were rechecked at an interval of 15 to 23 months following completion of training. Five of these retained their improvement, while only one showed worse than pre-training acuity.

4. There was no change in the refractive error, nor significant alteration in the ocular neuromuscular mechanism. It was thought that the improvement probably occurred because of an improved reception due to stimulation of the visual effort, as the best results occurred in those patients with a pretraining acuity less than would be expected from their refractive

error since 73 percent of this type improved.

5. Visual training has a definite, but limited, value in some myopic patients, preponderantly in those whose vision does not correspond with their known myopia. The effectiveness of visual training must be increased if it is to be generally applicable. Visual training merits further study from the ophthalmologist particularly in relation to progress in myopia.

640 South Kingshighway (10).

The optometrists associated with this project concur fully with the above results, interpretations, and conclusions.

NOTES, CASES, INSTRUMENTS

EPIDERMOID CYSTS OF LACRIMAL GLAND AND CARUNCLE

DANIEL M. ROLETT, M.D.
New York

The purpose in describing in detail these two cases of epidermoid cysts is to point out the differentiating characteristics (table 1) between the ordinary sebaceous cyst, the dermoid cyst, and the epidermoid cyst of which there is a rather general misconception, since even the

pathologists disagree as to the exact characteristics of these tumors.

An additional point of interest is the knowledge that according to Samuels,¹ dermoid tumors of the eye globe are relatively common; whereas, true dermoid cysts are of rare occurrence, probably being, in his opinion, rarer than intra-ocular retinoblastoma or sarcoma. The typical location of the cyst is in the upper temporal quadrant of the orbit near the lacrimal gland. These cysts may not be always well defined, which makes their

TABLE 1

POINTS FOR THE DIFFERENTIAL DIAGNOSIS OF SEBACEOUS, DERMOID, AND EPIDERMOID CYSTS

Sebaceous Cyst	Dermoid Cyst	Epidermoid Cyst
1. Lined with stratified squamous epithelium. Walls thin.	1. Lined with stratified epithelium. Walls thick and contain sweat glands and hair follicles.	1. Lined with stratified epithelium. Walls moderately thick.
2. Does not contain the fatty, sebaceous, and odorous material, that is typical of a sebaceous gland.	2. Invariably contains a cheesy material of a sebaceous character.	2. Contents are sebaceous but not odorous.
3. Contains layer upon layer of useless, nonfatty, odorless, infected keratin. Commonly called keratomas.	3. Contains sebaceous and sweat glands and hair follicles. The <i>congenital</i> dermoid cyst of <i>teratoma</i> type may encapsulate teeth, nails, glandular, and brain structure.	3. Contains no hair follicles, sebaceous or sweat glands.
4. Occur in the subcutaneous tissues of any part of the body, mostly in the scalp and in the lobe and on the posterior surface of the ear.	4. Develop along the embryonic clefts and lines of fusion. The <i>teratoma</i> type takes its origin from the embryonic germinal epithelium. Usually occur in the testes and ovaries.	4. (a) <i>Acquired</i> inclusion cysts mostly involve the orbital region and eyelids. These regions are the fusion sites of various embryonic structures. (b) <i>Congenital</i> inclusion cysts are located anywhere in the sebaceous tissues.
5. They are freely movable under the skin, although attached to the skin at one point.	5. Not freely movable. Solidly attached to the surrounding tissues.	5. <i>Congenital</i> inclusion cysts are not attached to the overlying skin. The <i>acquired</i> inclusion cysts are the result of an injury. In the process of formation they may carry a portion of the skin into the deeper tissues where the dermal cells subsequently form a cyst lined with squamous epithelium. They occur most commonly about the head and neck.
6. Increase rapidly in size, have a tendency to become infected, and are painful. They have an enlarged pore through which exudes a cheesy material, upon local pressure.	6. May have a hair sticking out. Do not become infected.	6. Possess a sinus from which a hair may protrude. Local pressure will express a cheesy material. Enlarge rapidly and frequently become infected.

diagnosis difficult. In a number of cases, diverticula of these cysts were found to extend deep into the orbit (Knapp,² Gifford,³ and Collado⁴).

The dermoid cyst tends to grow larger at the age of puberty. Depending upon its location, it may become tender and painful. Histologically, these cysts pre-

Fig. 1 (Rolett). An epidermoid cyst of the lacrimal gland. (A) Sebaceous gland. (B) Large cyst (Magnification $\times 56$).

sent the following essential features: (1) An inner epithelial lining; (2) in the wall are imbedded hair follicles; (3) sebaceous and sweat glands; (4) the inner epithelial lining may be partly replaced by granulation tissue and, in cases of secondary infection and ulceration, may contain epithelioid and giant cells. In some cases, degenerative changes are brought about by the increased intracystic pressure due to persistent accumulation of sebum and desquamated epithelium, New,⁵ and others have found that 49.5 percent of the acquired dermoids involve the orbital region and eyelids. The dermoid cysts will develop in these regions because they are the fusion sites of various embryonic structures.

Tumors of the caruncle, according to the literature, are exceedingly rare. The lacrimal caruncle and the semilunar fold take their origin from ectoderm and mesoderm. Although quite susceptible to trau-

ma and infection, they resist the invasion of pathologic processes. Wätzold⁶ found only six cases in 60,000 patients. Vail⁷ saw one case in 15,000 patients, and Serra⁸ compiled 136 cases from the literature, including three cases of his own.

CASE REPORTS

CASE 1

P. L., a man, aged 29 years, was first seen in March, 1946, complaining of tearing and burning of the right eye with occasional sharp, shooting pain in the right upper lid. There was a feeling of fullness and a sensation of the presence of a foreign body in the right upper quadrant of the eye.

Examination. The right eye revealed a slight puffiness of the upper lid with a tenderness on deep pressure at the upper outer corner. The bulbar conjunctiva, temporally and above, was congested with enlarged blood vessels. Eversion of the lid with simultaneous extreme rotation of the eye, nasally and down, revealed a mass at the outer upper quadrant of the eye, apparently nonadherent, but painful to touch. Several hairs were seen protruding from it. The rest of the eye was normal. Vision was 20/20. The left eye showed no pathologic condition. Vision was 20/20.

An operation was performed under local anesthesia. The lacrimal gland was

Fig. 2 (Rolett). An epidermoid cyst of the lacrimal gland. (A) Hair follicle. (B) Large cyst (Magnification $\times 220$).

located, and a medium-sized cyst, partly overlying it and partly fused with it, was located and removed intact.

Laboratory report. Gross examination showed the specimen to consist of a soft elliptical nodule, 4 mm. in its maximum dimensions and composed of gray and yellow tissue. Zenker fixation was used.

Histologically, the tissue is composed of collagen and fat covered by a delicate stratified squamous epithelium. Included in it is a cyst lined by thinned-out stratified squamous epithelium and filled with shreds of keratin. There is no inflammatory reaction about it, but in the corium, patchy edema and scattered lymphocytes, plasma cells, and large mononuclear cells with a few polymorphonuclears are noted.

Diagnosis. Epidermoid cyst of the lacrimal gland (figs. 1 and 2).

CASE 2

C. M., a man, aged 30 years, was first seen in May, 1946, at which time the patient gave the history of having noticed in the inner corner of the left eyeball a small swelling which had become progressively larger and more painful.

Examination. The right eye appeared normal. Vision was 20/20. In the left eye, the lids were normal but the bulbar conjunctiva, nasally, was moderately congested. Through this area coursed enlarged blood vessels. The caruncle and the area around it were red. The caruncle itself was about three times the size of the one on the right side, which was normal. Palpation and slight pressure over the area elicited pain and tenderness. There was also pain on extreme motion of the eye to either side. Slitlamp examination of the area revealed an enlarged porous opening through which a thick yellowish fluid exuded on pressure. The rest of the eye was normal. Vision was 20/20.

The clinical diagnosis at the time of the examination was infected cyst of the caruncle. An operation was performed, and the cyst was removed.

Laboratory report. Gross examination of a specimen of tissue from eyelid shows a spherical cystlike structure, 3 mm. in diameter. It is covered externally by an opaque, gray, large, shiny membrane that presents a few short fibrous

Fig. 3 (Rolett). An epidermoid cyst of the caruncle. (A) Sebaceous gland (Magnification $\times 56$).

tags. It is fixed uncut. Zenker fixation was used.

Histologically, the cyst has an epithelial lining made up of a thin layer of stratified squamous cells. It is filled with a quantity of keratin that is loosely arranged with spaces between the keratin layers, suggesting the presence of fluid. Outside the epithelium is a delicate fibrous wall containing a few compressed glands of modified sebaceous type.

Diagnosis. Epidermoid cyst of caruncle (fig. 3).

SUMMARY

Two rather rare cases of epidermoid cysts of the lacrimal gland and the caruncle have been presented with a description of their gross and histologic appearance. A brief review of the points of differential diagnosis between the most important cysts found in the orbit has been given.

THE VITAMIN IN OPHTHALMOLOGY

It is a pleasure to recommend *Le Vitamine in Oftalmologia*, by Giambattista Bietti. (Bologna, Licinio Cappelli, Editore, 1940. 539 pages, paperbound. Price, L.80). It is a comprehensive and readable treatise on the vitamins in ophthalmology. The ophthalmologist may well bog down at the mere thought of facing a book of more than 500 long pages on the vitamins, yet here is all he wants to know so clearly stated, so perspicuously arranged, that the contemplation of the monograph is truly refreshing. After a brief general introduction, each of the five vitamins important in ophthalmology, A, B₁, B₂, C, and D is thoroughly discussed in a separate chapter. Each chapter follows the same pattern. In a general part the biochemistry of the vitamin, its relation to the normal and abnormal function of the several systems of the body, and its therapeutic indications are discussed. In an ophthalmic part, the lesions and pathologic processes in the eye in which the vitamin or its absence may play a part are thoroughly discussed. Research on incompletely elucidated problems is described. A brief chapter is devoted to the vitamins of minor interest in ophthalmology, namely E, H, J, K, L, and P.

In a final chapter the correlation among the vitamins and their relation to hormones and ferments is discussed. Each chapter has an adequate bibliography and there is a general bibliography at the end of the book. Finally, as in the condensation of Toynbee's *Study of History*, there is a condensation of the condensation. A large table displays all important data at a glance.

SOCIETY PROCEEDINGS

Edited by DONALD J. LYLE, M.D.

COLORADO OPHTHALMOLOGICAL SOCIETY

January 18, 1947

DR. GEORGE STINE, *presiding*

DETACHMENT OF CHOROID AND RETINA

DR. GEORGE STINE read an interesting paper with a case report of this subject (published in the JOURNAL, 1947, Volume 30, July, page 987).

Discussion. Dr. Fritz Nelson offered the idea that the term choroidal detachment is really a misnomer as the condition actually is an edema of the retrochoroidal space. If a membrane detachment extends beyond the midline, it must be the retina which is detached since the vortex veins would always be ruptured with disastrous results if a choroid were detached to that extent. He had examined the patient referred to in the case report about one year after the first operation. The patient was doing very well; vision and fields were normal enough.

Dr. Stine (in closing) said that probably no more than two veins could be thus ruptured; however, there was no harm in doing a posterior sclerotomy and draining off the retrochoroidal blood.

RETROLENTAL FIBROPLASIA

DR. VON HALER BROBECK presented M. S., aged 20 months, one of premature twins who weighed two pounds at birth. The other twin died at birth. The exact gestation period was not known. The mother is a deaf mute. When first seen the child was obviously blind and had a marked nystagmus as well. Examination under anesthesia revealed large gray-white masses behind both lenses, with retinal vessels visible in the mass. A differential

diagnosis would have to be between retinoblastoma and retrolental fibroplasia. The child's birth history would seem to indicate retrolental fibroplasia.

Discussion. Dr. George Stine said that he had examined the child and that he felt the condition was certainly retrolental fibroplasia; that the prognosis for vision was certainly hopeless; and that he did not recommend surgery. Dr. Ralph W. Danielson agreed and added that most of these cases also have mental retardation so that the condition might be called, "cerebro-oculo-dysplasia," although the late Dr. Terry disagreed with this idea.

TUNICA VASCULOSA LENTIS

DR. WALTER A. OHMART presented C. A., aged 17 months, who was born prematurely at six months, weighing 2 lbs. 2 oz. The child remained in an incubator for three months; it was obvious almost from birth that vision was deficient. Development was quite normal in all other ways and the child now feels its way along when walking. The pupils react easily to light and accommodation, but it is obvious that the child has light perception only. Examination shows both lenses to be clear with several anterior synechias. Both fundi present either large masses in the vitreous or large retinal detachments, involving the whole retina in the left eye and lower half in the right. The optic-nerve heads cannot be seen in either eye, and X-ray films show no calcium. Examination under transillumination has been very unsatisfactory. The diagnosis is not determined, but the condition must be bilateral serous detachment, or retinoblastoma, or tunica vasculosa lentis.

Discussion. Dr. William Bane, who had examined the child, felt this case was not one of a malignancy. Dr. W. H.

Crisp felt it was most likely tunica vasculosa lentis and felt no surgery should be done. Dr. George Stine felt that since an error might be fatal, the worse eye should be enucleated to determine the tissue diagnosis and thereby possibly save the other. Dr. Leonard Swigert suggested that the history pointed toward a benign lesion, but that since the tumor seemed to be posterior to the lens, the condition pointed to glioma. Dr. Ralph W. Danielson said that X-ray studies are not conclusive. He has a patient in whom X-ray studies showed no calcium and yet, after enucleation, the bulb was found to be almost solid. Calcium would be evidence of degeneration of the tumor and thus of the cure and not the progress of the tumor. In this case, the loose retina does not point to glioma. Since the pupils dilate to light, there is strong evidence that the condition is one of retrolental fibroplasia. A glioma of this extent could only result in blindness. He suggested that a biopsy be done. Dr. Ohmart (in closing) said that the idea of a biopsy was very good and might be attempted.

FUNCTIONAL AMBLYOPIA

DR. MORRIS KAPLAN presented L. P., aged 11 years, who has complained of poor vision for a long time. Vision was 10/400 and 6/400. The child was in fifth grade and seemed to be able to maintain average grades. Ocular examination was entirely negative and refraction under atropine revealed $-3.50D$. in each eye, with no appreciable improvement in vision. A history of night blindness was questionable, and there certainly was no abnormal retinal pigment. Trial contact lenses brought vision to 20/25 in each eye. Was this a case of retinitis pigmentosa without pigment; or did it show a type of hysterical functional amblyopia?

Discussion. Dr. W. H. Crisp said that if refraction revealed a simple myopia with normal retinoscopic reflexes, then

conical cornea could be ruled out. Dr. William Bane said that the girl's school accomplishments would seem to indicate that no pathologic condition was present but that the condition was a purely functional ocular laziness and suggested the use of a collyrium with very stinging properties.

IRIDESCENCE OF ANTERIOR CHAMBER

DR. R. W. DANIELSON presented J. C., a man, aged 21 years, who had been seen five years before immediately after a dynamite-cap explosion at which time a jagged piece of copper was removed from the sclera near the ciliary body. Subsequent X-ray pictures were negative for a foreign body. The resulting vision was 0.8. Six months later the patient suffered a vitreous hemorrhage which resulted in retinitis proliferans and vision of light perception. Three days ago his eyes became red and painful and examination revealed the anterior chamber to be solid with an iridescent mass, which was filled with variegated crystals and presented an amazing color pattern in the beam of the slitlamp. The cornea was quite clear and no reflex could be seen past the opaque lens. Tension was 28 mm. Hg (Schiotz). His other eye has remained entirely normal.

Discussion. Dr. Leonard Swigert suggested the possibility of aspirating some of this anterior chamber material and determining its makeup.

UNUSUAL FORMATION OF RETINAL VESSELS

DR. W. H. CRISP presented Mrs. G. A. B., aged 55 years. When first seen, in 1931, the patient had shown great tortuosity of the retinal veins of the right eye, especially in the region of the disc, where there were several very prominent vascular loops, the highest of these having a prominence of about 5D. At that time the refraction of the right eye was nearly

normal; the visual acuity was 5/3, mostly, with correction; and the visual field was normal. There were several vague symptoms, perhaps attributable to a rather marked refractive difference between the two eyes. The retinal vessels of the left eye were somewhat tortuous, but much less so than those of the right eye. At various times between January, 1931, and May, 1938, the patient's eyes underwent moderate refractive change, but her condition showed generally very little modification. At one time some very tiny spots, probably hemorrhagic, had been noted in the retina, and the veins of the right eye showed marked kinking, but no narrowing, at the arteriovenous crossings. In June, 1938, Wassermann and tuberculin tests were negative, the blood pressure and basal metabolism were low. X-ray studies of the intracranial and facial region were negative as to pathologic conditions in the sinuses, orbit, and pituitary region, except as to the presence of a calcified pineal gland. There were some attacks of scotoma scintillans, and in October, 1938, there was some suggestion of moderate enlargement of the right blind spot. There were no other cranial symptoms such as headache, nausea, or dizziness. In September, 1939, the patient underwent a thyroidectomy. The vision of the right eye was then still 5/3, mostly, with correction.

The patient was in Washington for five years during World War II. In July, 1945, she came with the record of having noticed diminishing vision in the right eye for the past 8 or 9 months. The corrected vision at this time was: R.E., 5/6; L.E., 5/3. The psychiatrist who had examined the patient some years previously saw her again and reported finding only what he regarded as an anxiety neurosis so far as the neuropsychiatric condition was concerned.

By December, 1946, the vision of the right eye had fallen to less than 1/60,

while the vision of the left eye remained as before. The visual field was limited to a small central area. The right pupil still reacted briskly to consensual stimulus, the X-ray findings were still normal, and there was no significant neurologic evidence. The vessels on the right disc were perhaps slightly less prominent than at earlier records. The optic disc between the groups of prominent vessels was very pale. In the absence of other explanation, it had been conjectured that the ocular and visual changes arose from some sort of vascular anomaly behind the eye; although there was no ocular protrusion, no limitation of movements, and no fundus details suggesting Hippel's disease or other fundus disturbances beyond those here described.

Almost no vision remained in the right eye at the time of presentation of the patient, while no disturbance was found as regards the left eye, and the patient was otherwise in good physical condition.

Discussion. Dr. V. H. Brobeck asked if this might be angiomatosis. Dr. George Stine asked the feasibility of X-ray treatment. Dr. William Bane suggested that this must be a lesion in front of the chiasm as the left vision had remained normal. Dr. Crisp (in closing) remarked that the case did not resemble angiomatosis and that X-ray therapy might be considered.

Morris Kaplan,
Secretary.

COLLEGE OF PHYSICIANS OF PHILADELPHIA

SECTION ON OPHTHALMOLOGY

DR. BURTON CHANCE, *chairman*

PAROXYSMAL LACRIMATION WHEN EATING.

FRANK C. LUTMAN, CAPT. (M.C.),
A.U.S. (by invitation) read a paper on

"A Syndrome of Paroxysmal Lacrimation When Eating Associated with External Rectus Paralysis (the gusto-lacriminal reflex of 'Crocodile Tears')." An abstract follows:

Paroxysmal lacrimation when eating, which is occasionally seen as a sequel to a peripheral facial nerve paralysis upon the same side, is an abnormal form of reflex in which tearing accompanies salivation. The explanation for the abnormal facial movements following peripheral facial motor paralysis and other pathologic associated reflexes is also applicable here. From all cases now available, the evidence would suggest that this reflex tearing is established by either some of the regenerated axones to the salivary glands becoming misdirected to the lacrimal gland, or that single axones at the point of the lesion may branch and innervate both the lacrimal and salivary glands. However, the center for this reflex, if peripheral, remains obscure.

Two cases were described. The first was a congenital unilateral paroxysmal lacrimation when eating with a homolateral paralysis of the external rectus muscle. The second had bilateral external rectus paralysis and bilateral reflex tearing when eating. Upon reviewing the literature on lacrimation when eating, a third and similar bilateral case was found. In all three cases the condition was first noticed in infancy.

It is suggested that the pathologic processes in these three instances is produced by a pontine lesion, involving the abducens nucleus and the superior salivary nucleus of the seventh nerve, or by a lesion of the abducens nucleus and the genu internum of the facial nerve as it passes around the abducens nucleus.

The three cases of paroxysmal lacrimation when eating associated with external rectus paralysis are presented as evidence of the existence of a new congenital neuro-ophthalmologic syndrome.

For treatment, if the reflex tearing can be interrupted by cocaineization of the sphenopalatine ganglion, injection with alcohol offers a more permanent means of control. When indicated, the external rectus paralysis should be treated by tendon transplants from the superior and inferior recti muscles.

Discussion. Dr. Robert A. Groff: Captain Lutman has presented a rather interesting and new syndrome, so far as I am aware, when he adds to the familiar paroxysmal lacrimation during chewing movements, a homolateral external rectus paralysis.

I became interested in the syndrome without the external rectus palsy some 6 or 7 years ago when I saw a patient who teared whenever he ate an apple. This patient gave a history of having had a facial palsy from which he had completely recovered some 8 or 10 months before. As Captain Lutman suggested in the treatment of this condition, we, at that time, injected the sphenopalatine ganglion and produced temporary cessation of the phenomenon during the time the novocaine was acting. Since this was successful, the second injection was made with $\frac{1}{2}$ to 1 cc. of absolute alcohol, and for a period of about three months the patient was symptom free. After that he disappeared from the clinic, which may indicate that the difficulty did not return.

As to the association of the syndrome with a sixth-nerve palsy, rather than a facial palsy, I have had no personal experience. This is new, although I say it with hesitancy since I have not reviewed the literature. My reaction to Captain Lutman's explanation that this is caused by a central lesion is not in agreement. Certainly, the associated tearing with seventh-nerve lesions has been more or less proved to be a peripheral reflex phenomenon. The possible pathways are chordatympanic nerve, sphenopalatine ganglion, and then through the zygomatic

nerves to the lacrimal gland. It may be that in some way the fifth cranial nerve is involved, in view of the studies that Dr. Lewey and I carried out in connection with the Marcus Gunn phenomenon in which we demonstrated autonomic fibers in the branches of the fifth nerve which, when stimulated, caused eyelid movements after the third cranial nerve had been sectioned several weeks before. For this reason and because a central lesion would necessarily have to be minutely small to produce this syndrome without giving other neurologic signs, the entire phenomenon could better be explained on the basis of a peripheral perversion reflex. Furthermore, the fact that relief was obtained by injection of the sphenopalatine ganglion tends to support this view.

I wish to thank Captain Lutman for the privilege of discussing this interesting presentation.

Dr. Walter I. Lillie: I would just like to assure Captain Lutman that he has been fortunate in seeing so many cases because they are very rare indeed. I was very much interested as I have only seen one case with an external rectus paralysis and lacrimation. I feel as Dr. Groff does that it is a peripheral lesion. I personally do not see how one could conclude that there is pontine reaction in the region of the sixth nucleus where the seventh crosses around it. The pons is a very small portion of the central nervous system. A lesion large enough to include the seventh nerve crossing around the sixth nerve plus the salivary center produces a lot of contralateral motor and sensory disturbances in the individual, and that to my knowledge has not occurred. I think Dr. Lutman is to be congratulated on seeing as many cases as he has.

Capt. Frank C. Lutman (closing): With Dr. Lillie and Dr. Groff I also believe this is a peripheral reflex. A lesion of the pontine facial nucleus would produce a peripheral facial paralysis which

as I brought out in the paper is a requisite for this type of paroxysmal lacrimation to develop. As I understand Dr. Groff's contention, it would require two lesions to explain a combination of the abducens paralysis and the facial paralysis. To my mind it would be simpler to attribute this to a single lesion, and the point where the facial and sixth nerves are the closest together is in the pons.

However, as has been mentioned, this tearing is rather complicated, and I hope in the future a careful neurologic examination will be done in the new cases that are found.

I wish to thank Dr. Groff and Dr. Lillie for discussing the paper.

MENINGEAL FIBROBLASTOMA ARISING FROM SPHENOID BONE

DR. ROBERT H. TRUEMAN, presented an analysis from an ophthalmic point of view of the syndrome of meningeal fibroblastoma arising from the lesser wing of the sphenoid bone.

The historical aspects of suprasellar and parasellar meningiomas were considered with particular emphasis on the early observations of those arising from the sphenoid ridge.

The terms suprasellar and parasellar were defined, with a description of the sphenoid ridge. The anatomy of the region of the lesser wing of the sphenoid bone and sella turcica is reviewed and the pathology of meningioma was discussed.

The syndrome of early meningioma of the lesser wing presents such findings as optic atrophy, field changes, exophthalmos, involvement of ocular motility, sensory disturbances in the distribution of the second and first divisions of the trigeminal nerve, involvement of taste and smell, all on the side of the tumor. The appearance of pituitary and frontal lobe and motor and sensory symptoms and signs were also discussed.

The symptomatology of 56 cases was

analyzed to show that in 82 percent of them the first symptoms to appear were of an ocular character. The objective findings were then analyzed to show that 91 percent of the cases showed fundus changes, 86 percent showed visual field changes, 43 percent showed exophthalmos, and 38 percent showed some involvement of ocular motility. Among the findings, other than ocular, were trigeminal paresthesias, pituitary signs, involvement of taste and smell, frontal lobe signs, sensory and motor findings.

The X-ray findings were then discussed with particular reference to both generalized and localized changes among which are the erosions and the local and general hyperostoses.

The differential diagnosis was taken up in relation to intraorbital tumors, intrasellar tumors, aneurysms, optochiasmic arachnoiditis, gliomas, and craniopharyngiomas.

Discussion. Dr. Robert A. Groff: Dr. Trueman is to be congratulated upon his excellent presentation. Certainly, he has clarified the syndrome since Dr. B. J. Alpers and I first called attention to it some years ago.

The successful surgical removal of these tumors depends upon early diagnosis, because then the technical problem is simplified greatly. The lesion is small and, as a result, the opportunity for complete removal is much more favorable.

The picture presented to you includes cases of late diagnosis. In fact, some of them were made at a time when it was not possible for the surgeon to operate upon them. Let me give you the early signs which are sufficient to make the diagnosis. Early primary optic atrophy of papilledema, a visual field cut on the temporal side of the affected eye, and a top normal sella turcica are all that is necessary to demand further studies to verify the diagnosis by encephalography.

When a unilateral exophthalmos is de-

veloping in a patient, the possibility of a sphenoid lesser wing meningioma should be excluded first. X-ray films of the skull will aid in the diagnosis for, in my experience, the ridge shows definite thickening incident to tumor infiltration.

At the operation these tumors are interesting. They present either one of two types. The first is a bulbous growth, and the second is an en-plaque variety in which the tumor is flat, spreading over the surface of the dura. This latter type is usually associated with underlying bone infiltration which produces exophthalmos.

In order to cure these patients, it is necessary to remove the dura to which these tumors are attached. The bulbous variety offers a less difficult problem, from this stand point, than those which grow by spreading over the surface of the dura. The former, therefore, if not large can usually be removed completely. The latter are almost never removed completely and, therefore, recur. Since this type of tumor is a rather slow grower it is, in most instances, several years before a second operation is necessary.

When the bone has been invaded by the tumor, it is practically impossible to remove all of the involved bone because of the adjacent structures, internal carotid artery, nasal chamber, and sinuses and sphenoid fissure. Although a routine decompression of the orbit is done in those patients who have an exophthalmos, it does not relieve this sign completely but only partially.

Dr. Trueman stated that the cause for the exophthalmos is probably venous engorgement. As one observes the orbital contents in these patients, this explanation seems most likely, because the structures are edematous and under tension as though there was obstruction to the venous drainage system of the orbit.

A plea is made for the early recognition of these tumors. As Dr. Trueman has

stressed in his paper, when a patient comes to you with a slight primary optic atrophy, a temporal field defect in the same eye, and the X-ray pictures of the pituitary fossa are normal or top normal in size, have him investigated for the possibility of a lesser wing sphenoid ridge tumor without delay.

I wish to thank Dr. Trueman for the privilege of discussing his excellent presentation.

Dr. Walter I. Lillie: I would like to add my appreciation for Dr. Trueman's presentation, and to go one step further in what he has called the early part of the ocular syndrome.

The early thing is the retrobulbar neuritis syndrome on the side of the lesion. That is characterized by a lowering of the visual acuity. The visual fields will usually show a central scotoma, although they may have otherwise normal findings. This is the ideal time for the diagnosis to be made as it permits the neurosurgeon to enter and remove the tumor before it has been of long enough duration to have produced optic atrophy. Optic atrophy is irreversible, a condition which I wish to stress even stronger than Dr. Groff did.

The ophthalmologist sees these cases first, and he is the one responsible if they are delayed in reaching the neurosurgeon. In the early stages there is usually a normal fundus, and it is necessary to differentiate the lesion from an inflammatory type of condition or a toxic thing. Against that type of clinical syndrome, the onset of this, as Dr. Trueman has brought out and Dr. Groff has also stressed, is very insidious, and it progresses slowly. This indicates tumor rather than inflammation or vascular lesion. I feel that in these cases a very thorough neurologic examination is necessary, and should be requested by the ophthalmologist. I also strongly advocate doing an encephalogram early. I believe that this

is helpful in basal arachnoiditis in the sulcus chiasmatis, in lesions of the sphenoidal ridge, and in calcification. If it shows a massive type of space-taking lesion, it is a great aid. I concur with both speakers, but I feel that it should be stressed to take heed of the earliest eye syndrome and not to wait for the appearance of optic atrophy. If a case can be operated before atrophy has taken place, that patient has a very excellent chance to recover normal vision and that is the ideal end result.

Dr. Burton Chance was reminded by this history of a case of his own. He had been consulted by a lawyer who was engaged in a suit concerning the death of a woman after the collision of the automobile in which she was riding with her family, and a horsedrawn vehicle. Photographs made by bystanders absolutely confirmed the transportation company's contention that the company was not at fault, nevertheless a verdict was entered against the company.

Before the injured one's death it was declared that her sight had been destroyed, and that she was blind. Dr. Chance succeeded in obtaining the record books of an ophthalmologist, then deceased, who, 11 years before the accident, had been consulted by the woman. He recorded that she was blind in her right eye, because of complete atrophy of the optic disc, which he regarded as dependent on the high degree of progressive myopia of each eye. At that time there were no roentgen facilities, and further study was not made. Against the opposition of the plaintiff's family, an autopsy was obtained. Attached to the sphenoid was found a tumor of about the size of a large white grape extending by erosion into the orbit. Sandlike changes were felt over the surface of the tumor. By some strange sleight-of-hand the tumor was spirited away, and was never recovered!

Dr. Robert H. Trueman (closing):

Thank you, Dr. Groff and Dr. Lillie, for your discussions. You have both emphasized, as I have tried, the importance of the early changes in the diagnosis of this tumor.

I would like to call attention to the fact that this analysis includes cases representing all sizes of these tumors from the largest, in the early Cushing series, to the smallest in the series of Groff and Elsberg, and Dyke. This explains the varied types of clinical pictures found, from the very early fundus and field changes to bilateral blindness. While it is important to recognize the very early changes, one should know that, as the tumor grows, progressive changes occur, for it is possible that a case might just as well be seen late as early.

I would like to ask Dr. Lillie one question. In your experience, have you ever been able to pick up a case of meningioma of the lesser wing that had only a central scotoma?

Dr. Lillie: Yes, I have.

Dr. Trueman: That answers my question. Thank you.

NIGHT VISION FOR MILITARY PERSONNEL

ROBERT H. PECKHAM, PH.D., associate professor Physiological Optics, Department of Ophthalmology, Temple University Medical School (by invitation) presented a paper on "The Protection and Maintenance of Night Vision for Military Personnel."

This address is a report of the recommendations and research performed by the Vision Committee of the National Defense Research Committee for the military services during the war. The author acted as liaison officer between the Committee and the Bureau of Medicine and Surgery.

As a result of the deliberations of this group of civilian and uniformed scientists, the following action was undertaken by both the Army and the Navy.

1. All personnel were instructed in the use of the eyes at night, with especial attention to waiting for dark adaptation and to using the rods of the retina by "looking around things."

2. An attempt was made to supply night-combat personnel with red goggles, to preserve dark adaptation, and to permit the attainment of adaptation in lighted compartments.

3. All Navy personnel were examined to eliminate night-blind persons.

4. As a result of directed research, it was decided that sunglasses for day wear were necessary to permit the best night vision. These sunglasses were neutral in color, not green or amber, of 10-percent transmission, and polarized, with the plane of transmission vertical. Finally, no specification against transmission in either ultraviolet or infrared was included.

5. The facts learned during the war can be applied to peacetime pursuits. Since the effect of sunlight is to reduce the sensitivity of the retina, sunglass protection is recommended for fluoroscopists. The effect of sunlight is to reduce the efficiency by about 30 percent. Sunglasses are needed by all persons doing colorimetry, or any visual task involving comparative judgment. The effect of sunlight reduces retinal efficiency by from 20 to 50 percent, depending on the task.

In a determination of avitaminosis by measuring the course of dark adaptation, the effect of previous exposure to sunlight could conceivably be so great as to completely confuse the readings. Sunlight exposure can be effective for as long as three weeks after the period of exposure, and the effect of vitamin therapy can, therefore, be lost to demonstration.

All persons driving in dusk and at night, after a day in unprotected sunlight, will lose at least one half of their night visual efficiency, thereby rendering their driving dangerous and uncertain.

Discussion. Dr. Burton Chance, in commenting on the statement that persons exposed for long hours in the glaring sunlight were found to have distinct loss of power at night, remarked that he had noticed on his repeated visits to tropical islands that his native friends seldom would enjoy walking out with him at night, because they declared they could not see well at night.

On long voyages, as once on a sailing ship before he became an ophthalmologist, he noted how sailors, who had been most capable during the daylight hours, became less efficient during the night, especially after the periods when their daytime watches were prolonged.

In World War I, at his Army Hospital located at the seaside, men from northwestern climates who delighted in spending all the daylight hours on the beach would prefer to remain indoors at night. Dr. Chance believed that the daylight glare interfered with the photochemical reactions in the retina.

Dr. Walter I. Lillie: I would like to have a word before Dr. Peckham's closing remarks. We have read so much in the newspapers that the Negro race, the yellow race, and the brown race have much better night vision than the white race. I just wondered whether any of his investigations would prove or disprove those statements?

Dr. Robert Peckham (closing): We made a lot of measurements designed to distinguish racial differences. The first measurements were made by the Army for the purpose of selecting drivers of trucks and jeeps under blackout conditions at Fort Meyers. They deliberately chose members of the Negro race, because it was suspected that, being highly pigmented, they would have deeper choroidal pigmentation and be better able to see at night. The tests showed no difference. Many more careful and extensive tests

were made during the war until it was finally concluded that no one race showed any superiority of retinal sensitivity.

Some races were better able to perform out of doors at night, being better trained for night vision, because of their savage environment. At one time early in the investigations, we received a hurry up call from the British that the suggestion had been made that the Japanese were night blind. Because they were myopic, something ought to be the matter with them. Fortunately, a few retinal sensitivity records of Japanese students were available, but these showed no differences in retinal sensitivity.

During the Pacific campaign the Marines reported hearing Japanese broadcasts to the effect that the American Marines should stay indoors at night. It was reported that certain selected Japanese Shinto fighters had been selected for retinal operations, including the injection of secret drugs, and were then trained to be night killers. These people, it was boasted, had such tremendous retinal sensitivity that they could not go out of doors in the daytime, and therefore would not be seen. This sounded like a fairy tale, but it had to be investigated. It was concluded that it was in reality a falsehood, invented by the Japanese, because they had discovered that they had actually lost their night retinal sensitivity. They had occupied the islands for months, and even years, waiting and watching for us to come. They were aware of their night-vision loss, because we found their fox-holes literally lined with boxes of vitamin-A concentrates. We had ourselves tried the use of such concentrates, and found that they were useless to replace lost retinal sensitivity. Only time, and considerable time at that, will permit the retina to regain its lost sensitivity.

George F. J. Kelly,
Clerk.

Lake Geneva, Wisconsin

Directors: LAWRENCE T. POST, President; WILLIAM L. BENEDICT, Vice-President; DONALD J. LYLE, Secretary and Treasurer; WILLIAM H. CRISP, FREDERICK C. CORDÉS, DERRICK VAIL.

Address original papers, other scientific communications including correspondence, also books for review to *Dr. Derrick Vail, 700 North Michigan Avenue, Chicago 11, Illinois*; Society Proceedings to *Mrs. Katherine F. Chalkley, Lake Geneva, Wisconsin*. Manuscripts should be *original copies*, typed in *double space*, with wide margins.

Exchange copies of medical journals should be sent to *Dr. F. Herbert Haessler, 324 East Wisconsin Avenue, Milwaukee 2, Wisconsin*.

Subscriptions, application for single copies, notices of changes of address, and communications with reference to advertising should be addressed to the *Manager of Subscriptions and Advertising, 700 North Michigan Avenue, Chicago 11, Illinois*. Copy of advertisements must be sent to the manager by the fifteenth of the month preceding its appearance.

Author's proofs should be corrected and returned within forty-eight hours to the *Manuscript Editor, Mrs. Katherine F. Chalkley, Lake Geneva, Wisconsin*. Twenty-five reprints of each article will be supplied to the author without charge. Additional reprints may be obtained from the printer, the George Banta Publishing Company, 450-458 Ahnaip Street, Menasha, Wisconsin, if ordered at the time proofs are returned. But reprints to contain colored plates must be ordered when the article is accepted.

THE STUDY OF OCULAR MOTILITY

The members of the American Board of Ophthalmology are in a unique position to compare and evaluate the training of ophthalmologists from all over the country. There is, of course, the uniformity of the topics taught and examined in, as set forth by the prospectus of the Board. Naturally, too, there is a wide variation in the assimilation of the neces-

sary knowledge and techniques of ophthalmology by the candidates. The Board members have a very good idea of what institutions and preceptors turn out the best product. The quality of the teaching and opportunities is reflected in the standing of the candidates as a rule, although there are many exceptions.

Among the subjects that cause some

confusion and express the most variations in training throughout the country is that of ocular motility. This, however, should occasion no surprise because at the moment the leaders and teachers, themselves, are somewhat confused over the subject, which is inherently difficult to comprehend in all of its complexities. There is a modest conflict between investigators of the objective method of examination and diagnosis, as exemplified by Duane, White, and many others, and the followers of the neuromuscular and subjective method of examination and interpretation, as represented by Bielschowsky, Lancaster, Burian, and Adler.

The contributions of Duane and White have been important and helpful in the understanding and measurement of squint. The fact that it is a method of objective measurement with screen and prism has the fault that, in following this method, there is a tendency for one to discount or overlook the associated disturbed physiology or anatomic lesions in the ocular muscles or central nervous system underlying the objective signs. Adler brought this out very well in his Jackson Memorial Lecture, recently presented before the American Academy of Ophthalmology and Otolaryngology, when he discussed the "underaction" phenomenon in the nonfixing, nonparetic eye.

On the other hand the contributions of the neuromuscular school are probably more comprehensive and accurate, although more complex. The method of charting diplopia fields, advocated by the authorities, is not easy and the interpretation of these diplopia fields is certainly not automatic. Lancaster's chart with red and green goggles and targets simplifies the diplopia test and comes close to making it a satisfactory objective method of measurement and analysis. It needs a patient who is reasonably intelligent and who understands what is required of him.

Perhaps most of the candidates at the last examination of the Board followed more or less the objective method of measurement. Many had what has been lightly termed "P. trouble" or prism trouble, or "F.F.P." (fist full of prisms), and the usual difficulty of a fixation light and not enough hands was frequently encountered. Few were at home with diplopia tests, and while many showed some knowledge of the work of the neuromuscular school from their study and reading, not many had considered this side of the story intently.

The student suffers from lack of clear writing and description of both methods; especially the neuromuscular one, in our modern textbooks. The Duane-White method is only to be found in a few of the new textbooks on ophthalmology, and the neuromuscular method in this event is given scanty mention. The manual, *The Extrinsic Eye Muscles*, of the Home Study Course of the American Academy of Ophthalmology and Otolaryngology, prepared by H. Saul Sugar, covers both features of this somewhat thorny subject pretty well. There is, however, a need for a good and clear treatise. That this need is obvious is shown by the experience of the Board examination.

In view of the present and laudable state of controversy, no one method is entirely satisfactory in all cases or for all examiners. It would seem best, therefore, for the beginner to master the objective method first and then deeply study the "neuromuscular" methods until he has mastered them in so far as possible. In this way the best features of both methods will be preserved and followed, and a better interpretation of the patient's ocular muscle imbalance will result. Better and more complete methods of analysis will insure a more accurate diagnosis and will naturally result in better treatment.

Derrick Vail.

BOOK REVIEWS

OPHTHALMOLOGY, BEING SECTION XII OF EXCERPTA MEDICA. Amsterdam, The Netherlands. Excerpta Medica, Ltd. Price, \$15 per year.

A new abstract journal has been launched whose purpose it is to publish a complete survey of the entire medical literature. This is to be accomplished by 3,000 specialists who work under the supervision of 400 editors. One may subscribe for any number of the 15 sections which are published separately.

The first issue of Section XII, Ophthalmology, has been received. The preface states that completeness is the first objective the editors have set for themselves. Abstracts of articles of any importance will be at least long enough so that the reader may judge for himself whether he wants to refer to the original. When it is impossible to give a detailed abstract, the title will be given to draw the reader's attention to the existence of the original. The second objective is to produce a readable text for those readers who cannot find time to cover the world literature of their specialty in the original.

The coverage seems to be complete. The section on ophthalmology compares favorably with the prewar *Centralblatt*. There are 48 pages of competently written abstracts, all by men of the highest caliber. The abstracts, all in English, are so comprehensive that the general reader is adequately informed, and the investigator of a similar problem can judge whether he needs to consult the original. Not only are the major ophthalmic articles abstracted, but articles of ophthalmic interest are taken from journals which most specialists would not think of combining. Most of the publications abstracted in the first issue appeared in 1946, a few as early as 1940. The preponderance of articles from 1946 justifies the belief that

abstracts will appear rather promptly.

It is perhaps inevitable that the general reader who uses this journal as a substitute for the original literature will find himself exhausted. Such concentrated diet engenders a state comparable to museum fatigue. The material is, after all, a collection of condensations made by many men and presumably not altered by one editor in the interests of unity of viewpoint. It is not the function of an editor to evaluate critically the data presented by the original author, but he can be of tremendous help to the general reader by pointing out, often with the utmost brevity, the significance of data which the original author presents with comments that are only adequate for a fellow-worker but cryptic for the general reader.

F. H. Haessler.

RETINAL STRUCTURE AND COLOUR VISION. By E. N. Willmer, Sc.D. Cambridge, University Press, 1946. 231 pages, 77 illustrations (4 in color), index, and bibliography. Price, \$4.50.

This monograph presents a novel, stimulating, and plausible theory of retinal function. The increasing interest in this little understood field should lead to further research to test its validity and implications. Willmer's thesis, in simplified outline, is this:

The central fovea is dichromatic when precisely tested with 20-minute test objects. The color confusions that result from the relative insensibility to blue are typical of tritanopia. This sensitivity of the fovea to but two color factors simplifies the analysis of the mechanisms involved. The bipolar cells of this area include not only the midget type, characteristic of the direct-cone pathway, but also

flat bipolars, typical of a rod-cone pathway. Hence the deduction: that the fovea has receptors belonging to the rod family of cells, dependent on visual purple for their spectral sensitivity, though incapable of the rapid accumulation of visual purple necessary for dark adaptation. The cone-midget bipolar unit is then the "red receptor," while the "green receptor" is formed by the combined action of cones and nonadapting rods relaying centrally through the flat bipolars.

The perception of blue appears connected with the normal rod-mop bipolar pathway, for in blue light acuity is higher in the retinal periphery than in the fovea. Since light adaptation increases the sensitivity to blue, the light-adapted rod, which has experienced some bleaching of visual purple, may be considered the "blue receptor." This view is supported by the interrelationship of tritanopia and night-blindness, the sensitivity to dim light in tritanopia being about 0.55 percent of normal. A 5-mm. blue disc only appears full blue when the object approaches near enough for the image to involve the parafovea.

Inhibition of the adapting rods by the cones, suggested by the electroretinogram, reduces rod activity during daylight and prevents dazzle. Rod-cone antagonism

may be likened to that of the sympathetic and parasympathetic systems. From the nature of their dendrites and the action of drugs, the cones would seem cholinergic and the rods adrenergic.

When the energy values in the scotopic and photopic visibility curves are related to impulse frequency, the results reasonably explain the characteristics of the color chart, hue steps, and color variations at different light intensities and by addition of white. In this respect the application of Willmer's theory gives significance and coherence to what has hitherto seemed inexplicably bizarre.

In birds, color vision probably depends on three types of cones, but there is no such evidence in man. Willmer's interpretation, though admittedly speculative, has the advantage of being based on what has been already demonstrated in human visual physiology. A possible mission of the Eye Banks could be the further advance of our knowledge in this field by the procurement of eyes of known types of color blindness for the study of their retinal structure and photochemistry by especially qualified investigators—a direct approach, previously unfeasible, that promises much.

James E. Lebensohn.

ABSTRACT DEPARTMENT

EDITED BY DR. F. HERBERT HAESSLER

Abstracts are classified under the divisions listed below, which broadly correspond to those formerly used in the Ophthalmic Year Book. It must be remembered that any given paper may belong to several divisions of ophthalmology, although here it is mentioned only in one. Not all of the headings will necessarily be found in any one issue of the Journal.

CLASSIFICATION

1. General methods of diagnosis
2. Therapeutics and operations
3. Physiologic optics, refraction, and color vision
4. Ocular movements
5. Conjunctiva
6. Cornea and sclera
7. Uveal tract, sympathetic disease, and aqueous humor
8. Glaucoma and ocular tension
9. Crystalline lens
10. Retina and vitreous
11. Optic nerve and toxic amblyopias
12. Visual tracts and centers
13. Eyeball and orbit
14. Eyelids and lacrimal apparatus
15. Tumors
16. Injuries
17. Systemic diseases and parasites
18. Hygiene, sociology, education, and history
19. Anatomy, embryology, and comparative ophthalmology

1

GENERAL METHODS OF DIAGNOSIS

Jaques, R. The size of the blind spot in aphakic eyes. *Ophthalmologica*, 1947, v. 113, June, pp. 365-374.

The author measured the horizontal and vertical diameter of the blind spot in 27 emmetropic and 29 aphakic eyes. Campimetry with lenses correcting the aphakia proved difficult and unsatisfactory apparently because the strong lenses produced marked and inconsistent distortion of the perimetric findings. The author, therefore, resorted to campimetry without correcting lenses, using a round white fixation target two centimeters in diameter. The size of the blind spot was determined at one meter with a white target one centimeter in diameter, moved from the seeing into the blind area. Under these conditions, the normal blind spot of the aphakic eye proved to be about one-third larger than that of the emmetropic eye. This empirical result tallies with the theoretical one, since the refractive power of the emmetropic eye (58.64D after Gullstrand) is about 1.35 times the re-

fractive power of the aphakic eye (43.05D). Peter C. Kronfeld.

Vaško, A., and Peleska, M. Visual diagnosis of eye diseases by means of infrared radiation. *Brit. Jour. Opth.*, 1947, v. 31, July, pp. 419-421.

In their studies the authors illuminated the eye with infrared radiation of a wave length exceeding 8,500 Å. The image was then projected by means of an objective lens onto the photoelectric cathode of an image converter. This converter transformed the infrared image into a visible image on a fluorescent screen. This image on the screen was then photographed.

Morris Kaplan.

2

THERAPEUTICS AND OPERATIONS

Andrews, G. W. S. Distribution of penicillin in the eye after subconjunctival injection. *Lancet*, 1947, v. 1, May 3, pp. 594-596.

Subconjunctival injections of 50,000 units of pure sodium penicillin were made in the left eyes of four rabbits.

The bleb was absorbed at the end of three hours and the eyeball appeared normal at the end of six hours. The blood serum contained four units per cc. in one half hour and reached zero at the end of two hours. The concentration in the aqueous reached 16 units per cc. in one half hour and fell to one unit per cc. at the end of four hours. The cornea contained 170 units per cc. one half hour after the injection and fell to 1.7 units per cc. at the end of four hours. The levels in the optic nerve were high, but fell rapidly. The uninjected fellow eye had a similar distribution, but with lower levels of concentration.

Irwin E. Gaynon.

Angius, T. and Mojne, G. Plesiotherapy (contact radiation) in ophthalmology. *Rassegna Ital. d'Ottal.*, 1947, v. 16, March-April, pp. 107-130.

The authors report upon 91 cases of various pathological conditions of the eye, especially corneal disease, treated by contact doses of roentgen radiation. Small doses were especially effective in herpes of the cornea and subacute, torpid keratitis with decreased corneal sensitivity. The treatment should be applied as early as possible and dosage should never exceed 400 r. The treatment is interrupted as soon as improvement is observed, even after one application, lest re-activation of the disease should occur.

Eugene M. Blake.

Apple, Carl. Instruments for use in ophthalmic surgical procedures. *Arch. of Ophth.*, 1947, v. 37, May, p. 652.

The author's corneal scissors are a modification of the Walker scissors. The lower tip extends 1 mm. beyond the upper tip; the extended part is 1 mm. wide; the extreme end is rounded, and the surface is highly polished. This enables the operator to

enter the anterior chamber with less difficulty and without trauma to the iris after the original section of the cornea.

In the iris redepositor described, the handle may be rounded or square; the round handle enables the operator to rotate it between the thumb and the index finger. The redepositor portion is bent at an angle of 115 degrees and is 5 mm. long and 2 mm. wide; the extreme end is rounded and dull, and the surface is highly polished. (2 figures.)

R. W. Danielson.

Bellows, J. C., Burkholder, M. M., and Farmer, C. J. Streptomycin in experimental ocular infections. *Proc. Soc. Exper. Biol. and Med.*, 1947, v. 65, May pp. 17-18.

On rabbits anesthetized with intravenous injection of nembutal the penetrability of streptomycin through the cornea is increased by abrasion, inflammation, ion transfer and wetting agents. No local toxic effects were noted when saline solutions of streptomycin containing 10,000 ug per cc., were used. Concentrations of 50,000 ug or the dry powder caused delayed healing. Intraocular injections of 1,000 ug in 0.1 cc. saline solution were well tolerated. Concentrations of 25 to 300 ug were therapeutically effective (up to 6 to 8 hours) against a virulent strain of *Streptococcus pyogenes*. Corneal ulcers were prevented in *Bacillus pyocyaneus* infection by three applications at two-hour intervals of a saline solution containing 10,000 ug of streptomycin per cc.

H. C. Weinberg.

Benedict, W. L., and Henderson, J. W. Sodium sulfacetimide. *Amer. Jour. Ophth.*, 1947, v. 30, August, pp. 984-986. (9 references.)

Bonazzi, A. Surface anesthesia with Farmocaine. *Rassegna Ital. d'Ottal.*, 1947, v. 16, May-June, pp. 224-227.

Farmocaine is a new surface anesthetic presented by the firm of Farmitalia. Employed in solutions varying in strength from one-fourth to 2 percent the drug produces rapid anesthesia, with no effect upon the intraocular pressure, pupillary diameter, or the epithelium. It is of low toxicity and boiling it for 10 minutes at 100 degrees C. does not destroy its action.

Eugene M. Blake.

Esente, Ivan. First therapeutic experiments with paraaminobenzoildithethylaminoethanol chloride (Recor-cain) used intravenously in ocular diseases. *Riv. di Oftalm.*, 1946, v. 1, Nov.-Dec., pp. 671-678.

Recoraine was first used in 1941 by Dos Ghali, Bourdin and Guiot. One percent solutions were given intravenously in asthma, pulmonary embolism, and angina syndromes, dyspnea of emphysema, and tuberculosis. With and without additional atropine administration, the drug proved to be useful in gastric neuroses and gastric ulcers, it was used in carbon monoxide poisoning and in hyperthermic coma. The drug acts as a depressor of the respiratory center which, with higher dosage, may become paralyzed. Muscular contractions become rarer, the action on peripheral nerve centers is inhibitory. An antihistaminic action was ascribed to the drug by State and Wangenstein, 1946. Through the vegetative centers the drug produces a transient heat sensation and slight drowsiness, or sleep. Ocular pain and headache are relieved for shorter or longer periods. Lutten, Roumer, Giraud and Ferran were able to combat eclamptic amaurosis by intravenous administration of recoraine.

Esente used it in painful glaucomas, where the results mostly were satisfactory (no statistics). Pain was relieved and intraocular pressure was reduced for much longer than the time during which the drug was administered. Simultaneous use of miotics may enhance these effects. The doses given varied between 10 and 100 centigrams.

K. W. Ascher.

Filatov, V. P. Problems of tissue therapy. *Oftal. Jour. (Odessa)*, 1946, pt. 3, pp. 1-6.

The experience and research with tissue therapy during the war eliminated the chief objection to this method of therapy, that is, the lack of sterility in transplanted tissue. It was found that the therapeutic effect of tissues preserved on ice is not diminished by boiling, and by autoclaving at 120 degrees for one hour. This fact was demonstrated experimentally by Skorodinskaja and Tarasova in restoring skin defects on white mice, and clinically in such diseases as myopic chorioretinitis, uveitis, and trachomatous pannus. Inasmuch as in boiled extracts albumens are present only in insignificant amounts, heterogeneous tissues may be used without fear of anaphylactic reactions. The effectiveness of extracts of green leaves, preserved in darkness, further simplified this form of therapy in making possible their administration orally or by rectum. The value of this form of therapy has been demonstrated in hundreds of cases of trachoma, where it was used in combination with repeated expression. Tuberculous, parenchymatous, herpetic, and trachomatous keratitis react to this therapy very well. It is of value in traumatic uveitis and vitreous opacities. It constitutes the chief therapy in retinitis pig-

mentosa. It is useful in all types of optic atrophy, and in glaucoma. An incidental effect is the improved function of the uninvolved eye. It has proved valuable in a number of general diseases such as experimental tuberculosis in animals, lupus, scleroderma, neuritis, neurodermatitis, and post-traumatic contractures and limitation of movement. During the war this therapy was used and found effective in ulcers of the stomach, in lesions of the peripheral nervous system, in epilepsy, in typhus, brucellosis, pellagra, and leprosy. On the basis of experimental and clinical investigations the following hypothesis is presented. Tissues separated from the organism and subjected to an atmosphere unfavorable to life undergo biochemical changes; as a result of these changes they produce substances which stimulate the biological processes. These substances, when introduced into an organism, act as stimulants of its biologic processes; they stimulate cellular metabolism, and thus physiologic functions; in case of disease they augment the organism's regenerative powers and resistance to disease. Biogenic stimulants, products of biochemical changes, arise also in organisms placed in environments which make life difficult, but not impossible; such a reaction may play a role in the process of evolution. The crisis in acute infections is an example of unfavorable conditions leading to biochemical changes with the development of stimulants. Conditions leading to the development of biogenic stimulants are varied; preservation of animal tissues on ice, preservation of plants in darkness, the action of ultraviolet light, exposures to X ray and fever therapy. Biogenic stimulants are the products not of the dead cell, but of the living cell fighting for

life. It has been shown in botany that traumatized cells produce traumatic acid, belonging to the dicarbon group. It is possible that the biogenic stimulants are of a similar nature. Since they tolerate a high temperature they could not be albumens or ferments. This hypothesis may explain the beneficial effect of mud therapy, which Filatov believes is due to the biogenic stimulants accumulated in the mud by the living substances which took part in its formation. Autoclaved extracts of seashore mud prepared at the Institute produced effects similar to those of tissue extracts. Agricultural experiments have shown that preliminary processing of seeds of corn, wheat, and oats with extracts of preserved tissues hastens their sprouting, ripening, and productiveness. Ray K. Daily.

Haffly, G. N., and Jensen, C. D. F. **Method for the maintenance of sterility of ophthalmic solutions.** Arch. of Ophth., 1947, v. 37, May, pp. 649-650.

The authors use 20-cc. rubber-capped vaccine bottles for their ophthalmic solutions. The rubber cork is painted with zephiran chloride before each removal of solution with a syringe and needle.

R. W. Danielson.

Halbron, P., and Aitoff, H. **Nylon thread in ocular surgery.** Ann. d'Ocul., 1947, v. 180, March, pp. 158-167.

The relative advantages of absorbable and nonabsorbable sutures are discussed in detail. Ocular sutures should be resistant, easily manipulated, have a smooth surface, should not swell, should not produce inflammatory reactions and should be easily sterilized. The form of nylon currently used for suture material is polyheamethylene adipamide. It has a density of about

1.5, a refractive index of 1.55, its molecular weight varies between 10,000 and 20,000, it is not affected by ordinary temperatures or the usual solvents, equally resists alkalis and diluted acids, and has a resistance to traction which is superior to silk. Multibrin, a braided nylon, is more supple, is more adequately knotted and has an elasticity superior to natural silk. Nylon sutures are better tolerated by the tissues than silk; no reaction has been observed after three weeks. The sizes usually employed are 0.1-mm, 0.15-mm, 0.2-mm. Sterilization may be accomplished by wet heat or dry. In cataract extractions a 0.15-mm. thread is used in the superior rectus for fixation, and in conjunctival and corneo-scleral suturing. Knots should be firmly tied because the material is slightly elastic. Corneo-scleral sutures fall out about the tenth day. In muscle operations the 0.15-mm. or 0.2-mm. sizes are used and should not be cut too short. In eviscerations, or retinal detachments the 0.15-mm. sizes may be used. In skin sutures, nylon is of special value because of its size and because it slides easily in the tissues. (13 references.)

Puglisi-Duranti, G. Vaccine-therapy (spirochetic vaccine of Hilgermann) in some cases of ocular syphilis. *Boll. d'Ocul.*, 1946, v. 25, July-Sept., pp. 407-420.

Hilgermann vaccine is prepared from strains of nonvirulent polyvalent spirochetes and is used together with chemotherapy to secure sterilization of the system and to prevent the late nervous manifestations. The writer treated seven patients, two of whom had anterior uveitis, four optic neuritis, and one total paralysis of the third cranial nerve, with varying degrees of success. The treatment is to be tried in neurophthalmic syphilis which very frequently is a forerunner or concomitant of grave forms of neurosyphilis.

Melchior Lombardo.

Quilliam, J. P. Di-isopropylfluorophosphonate (DFP); its pharmacology and its therapeutic uses in glaucoma and myasthenia gravis. *Post-Grad. M. J.*, 1947, v. 23, June, pp. 280-282.

Aqueous solutions of DFP are unstable because of hydrolysis. DFP combines irreversibly with choline esterase. Choline esterase activity is restored when the enzyme protein is resynthesized. Peanut oil is used as a vehicle. In the normal eye DFP may cause miosis that lasts three weeks with ciliary spasm for three to seven days. It overcomes atropine easily. In glaucomatous eyes, a 0.1 percent solution, is effective for 12 hours. A 0.1 percent solution of DFP is as effective as 1 percent esserine. Irwin E. Gaynon.

Schubert, Franz. The effect of iodine baths on diseases of the eye. *Wiener*

Klin. Wchnschr., 1947, v. 59, July 4, pp. 435-436.

The author who practices in Bad Hall, Austria, reports his favorable experiences in treating certain eye diseases of patients who took the cure in this community which harbors springs containing iodine. Tuberculous inflammations like keratoconjunctivitis ex-cematosa and chronic tuberculous iritis showed marked improvement. The progress of chorioretinitic lesions could be stopped with subsequent improvement of the visual acuity. The bath-cure hastens the absorption of vitreous opacities, especially those caused by hemorrhages. The large group of arteriosclerotic diseases which lead to retinal hemorrhages and to retinal degeneration responds favorably to an extensive iodine cure. So do cases of partial venous thrombosis. Interstitial luetic keratitis improved under the treatment. The article emphasizes the necessity of repeated annual visits. It is not made clear how the water is administered nor how it is believed to act.

Max Hirschfelder.

Thomas, G. J., and McCaslin, M. F. Pentothal sodium in ophthalmic surgery. Arch. of Ophth., 1947, v. 37, April, pp. 452-458.

Pentothal sodium by intravenous injection is an important anesthetic for ophthalmic surgery. The administration is simple, the induction is short and pleasant, the depth of narcosis is controllable, the operative field is free of the anesthetist and his equipment and the intraocular tension is reduced 40 to 60 percent.

Pre-anesthetic medication consists of the administration of morphine and atropine and the local use of cocaine. The technique of administration and the complications are discussed. Pento-

thal sodium should not be employed if there is pronounced interference with the respiratory function, if there is bronchiectasis, severe anemia or shock and its use is not advisable in children under seven or eight years of age. The drug should be administered by a thoroughly trained anesthetist, who is competent to deal with any situation that may occur. John C. Long.

Vidal, F., Brodsky, M., and Travi, O. C. Miosis due to carbaminoylcholine in patients with retinal angiosclerosis. Arch. de Oft. de Buenos Aires, 1946, v. 21, Oct.-Nov., p. 350.

In 31 cases of retinal angiosclerosis the instillation over the corneal limbus of one drop of a 0.33 percent solution of carbaminoylcholine chloride produced a miosis. It began in about five minutes as in normal individuals but reached its maximum in 30 minutes and lasted longer than in normal eyes. (Bibliography.) Plinio Montalván.

Vidal, F., and Villa, E. Practical modifications of the Schiötz tonometer. Arch. de Oft. de Buenos Aires, 1946, v. 21, Oct.-Nov., p. 313.

The authors modified the Schiötz tonometer by substituting two threaded bolts for the screw that holds the disc of the plunger, painting red and black the markings of the scale, and attaching two cupped discs for the fingers when holding the instrument. (Illustrations and bibliography.)

Fourteen Schiötz tonometers of Austrian, American, French, German and Swedish manufacture were tested

with a modified torsion scale and all of them were found to be inaccurate. (Bibliography.) Plinio Montalván.

Vouters, J. Basal scopolamine-morphine-ephedrine anesthesia in ophthalmology. *Ann. d'Ocul.*, 1947, v. 180, March, pp. 149-157.

S-M-E anesthesia is recommended in major ophthalmic operations in nervous patients especially if immobility of the eye is important, as in glaucoma and cataract surgery, and in infants. It is useful in some enucleations, eviscerations, and operations for intra-ocular foreign body, in operations of long duration such as retinal detachments, lid plastics, orbital exenteration, and in dacryocystorhinostomy.

One hour before operation two cc. of a French proprietary drug called Nargenol is injected subcutaneously. This solution contains dihydroösycodeinone 2.00, scopolamine camphosulfonate .0005 ephedrine camphosulfonate .002, spartine .005, and physiological salt solution q.s. ad. 2.00. In infants, one fifth cc. is injected and in a child of five years, one cc. is used. The advantages of this type of anesthesia are that it leaves a clear field for surgery, the period of anesthesia is reduced and there is no agitation nor vomiting. Occasionally slight respiratory irregularity may appear 45 minutes after injection, which can be overcome by caffeine or lobeliene. Under certain conditions the anesthetic solution may be increased to four cc. without danger. Barbiturates and bromides tend to accentuate its effect. Chas. A. Bahn.

Ray K. Daily.

Arjona, J., Stenopeic hole and its use. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1946, v. 6, May, pp. 425-435.

The stenopeic hole has a number of uses in ophthalmology, some of which are practical and others experimental. Its principal clinical use is to distinguish between the low vision of a refractive error and disturbances of the transparent media, retina or optic pathway. The basis of its action is a reduction to a minimum of the circles of diffusion on the retina. These circles are larger the higher the degree of ametropia. The stenopeic hole may be used as a loupe for viewing near objects for the same reason. To avoid movements of the eye the hole is used after operations for retinal detachment. Its use has been recommended for albinos.

It also has experimental uses. In Mile's experiment, when a distant light is seen through the stenopeic hole, which is moved forward to the anterior focal plane, one of three things may occur. The light remains fixed, it moves in the same direction as the hole, or in the opposite direction. In the first case the eye is emmetropic, myopic in the second and hypermetropic in the third. This experiment was the basis of the kinescopy, wherein the movement of the light is neutralized by means of lenses. In Scheiner's experiment two stenopeic holes are placed horizontally in a screen less than a pupillary diameter apart. When a pin is viewed through the two holes while the eye fixates a nearer object the pin is seen

double and diplopia is direct. When the eye fixates a more distant object diplopia is crossed. This experiment proves the existence of accommodation and is used to measure its amplitude. Several diagrams are shown for the better understanding of these experiments.

Burian, H. M. Sensorial retinal relationship in concomitant strabismus. *Arch. of Ophth.*, 1947, v. 37, May, pp. 618-648.

In this portion of a paper too long to print in one issue of the Archives, the author discusses the origin, literature and nomenclature of anomalous correspondence. This is an excellent paper for those who are interested in this subject and already understand some of the fundamentals. Any abstract would be inadequate. (106 references, 9 figures, 2 tables.) R. W. Danielson.

Carreras Matas, B. A concept of the degree of myopia and hypermetropia in an astigmatic eye. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1947, v. 7, April, pp. 348-350.

As a formula for the measure of myopia or hyperopia of an astigmatic eye Matas uses the sum of the diopters of sphere and half the diopters of astigmatism. He demonstrates the mathematical derivation of this formula.

Ray K. Daily.

Gallagher, J. R., Ludvigh, E. J., and Martin, S. F., and Gallagher, C. D. Effect of training methods on color

vision. *Arch. of Ophth.*, 1947, v. 37, May, pp. 572-582.

In various surveys it has been found that from six to eight percent of unselected males are unable to make the proper responses to a series of color vision test plates. Regardless of the reliability of various testing methods or the desirability of altering present standards, there still remains the problem whether the color vision of those who fail to pass these tests can be modified. Whenever large numbers of persons are excluded either from a branch of the armed services or from a civilian occupation because of a physical disability, there will develop a demand from those affected that the disability be remedied or that the standards applying to it be lowered. In the problem at hand, the rejection of many otherwise well-qualified men has led to efforts to improve the color vision of these rejectees so that subsequently they might be able to pass the color vision tests. In an effort to determine the effect of training methods, a group of subjects previously identified as being deficient in color vision was studied.

Forty-nine subjects who had been selected as weak in color vision on the basis of responses to the American Optical Company pseudo-isochromatic test plates were subsequently given training on those test plates until all but 4 could satisfactorily pass that particular color vision test. However, only 6 made perfect responses to all the plates in the very similar Ishihara test, and the scores on a color desaturation test, which also had not been practiced, did not improve. A retest on the American Optical Company plates several months later showed a considerable diminution in ability to make correct responses to these plates and indicated

that the effects of this type of training may not long persist.

Color vision training apparently is successful in enabling most persons with weak color vision to respond correctly to such a test as the American Optical Company plates or the desaturation test herein described, but from this study there is no evidence that either of the training methods used improved the capacity to discriminate between colors in a situation other than the one in which training was given. (6 tables, 2 figures, 6 references.)

R. W. Danielson.

Gát, L. A new subjective test for astigmatism. *Ophthalmologica*, 1947, v. 113, Feb., pp. 93-105.

A dial test for astigmatism has been combined with Scheiner's double pinhole test for ametropia. The dial recommended by the author consists of a heavy, black, double cross, the strokes of which are two centimeters wide and placed two centimeters apart. In the center the strokes are interrupted except for four black squares (two centimeters square) at the actual crossing places of the horizontal and vertical strokes. These central squares apparently facilitate the observation of the various distortion phenomena due to astigmatism. The dial can be rotated around the axis laid through the center of the cross. It is viewed through a double pinhole (1-mm. holes, placed 2.5 mm. apart). Ametropia causes diplopia which, because of the construction of the dial, is easily noticed and described. The author stresses the accuracy of the method. "It is possible to find axis divergence of 2° and astigmatic ametropia of 0.25D." The test requires "comparatively little intelligence and power of observation."

Peter C. Kronfeld.

Giudice, Mario del. Ocular allergy. *Rev. Brasileira de Oft.*, 1947, v. 5, June, pp. 209-218.

In various parts of Brazil, where the tree is native, and also in India, where it is cultivated, the natives make a household remedy for infestation by lice by grinding the seeds of the first of one of the anonaceae, *Rollinia sylvatica*, and mixing it with pork fat. The mixture is rubbed into the hairy scalp and the hair is subsequently washed with soap and water. The author reports several cases of allergic reaction in the eyelids and conjunctiva, with abundant tearing, slight mucous secretion, intense photophobia, burning, and itching. Alleviation may be obtained from instillation of adrenalin solution. (One illustration, references.)

W. H. Crisp.

Hartmann, E. The psychology of vision. *Ann. d'Ocul.*, 1947, v. 180, April, pp. 193-205.

Hartmann presents a brief but comprehensive analysis of the mental aspects of the process of vision. We seldom see what we think we see. Retinal images differ greatly from visual interpretations. The latter are composed of our proprioceptive stimuli, intellectual concepts, past experience, and hereditary factors. One may ignore or eliminate parts of the pattern of visual perception, as is done by one with strabismus or in using the microscope. We may add to our visual perceptions as in viewing cartoons. Personalities such as Li'l Abner or Jiggs, are in reality only a few printed strokes and devoid of detail.

In the perception of colors our sense of values is modified by the surroundings of the object perceived. Psychologically, we associate colors in an orthodox manner. We know that violet

is a red-blue but we do not realize red as violet-orange. The same is true of complementary colors. We also associate color values with emotional values. Red suggests the rich, sumptuous, or gay; violet, the majestic; black, sadness; certain greens, outdoor life. The association of red with heat or warmth, blue with cold, is used in the color schemes of homes and factories.

In the concept of form, visual interpretation plays an important part. In the steps of Schroeder or the cube of Necker the third dimension of depth, which does not exist on the retina, is added by our imagination. Knowing that money is round, our consciousness does not register the many ellipses that are actually formed when discs are viewed at different angles.

Our interpretation of direction depends on numerous factors. The actual retinal image, our visual fields as related to parts of our body, as well as our proprioceptive sensations which emanate from the muscles of our eyes, neck and trunk, all enter into this complex visual function.

In estimating the size of objects we are guided by the macular and peripheral image sensation, combined with angulation. A small object in the sky may be first recognized as an airplane but soon it is known to be a gull.

The estimation of distance involves not only our central and peripheral retinal visual sensation, but also our judgment gained through past experience, and color differences such as zones of shadow or the bluish color of the air. Paralactic displacement and linear perspective also enter into this complex mental process. After years of blindness those who have regained sight have at first a very poor sense of distance.

Reversal of the inverted picture on

the retina does not actually exist as the visual perceptions involved are really reversed in the calcarine region. Rapidly moving objects when photographed show a blurred course which does not exist in vision. Binocular single vision is obtained by merging the two retinal images to give the inference of depth. If the monocular components are identical, the binocular perception does not differ from the two components. If slightly different, the binocular perception is intermediate; but if the monocular components differ too widely, binocular perception is impossible, and one of the images is either neutralized, or both images strive for supremacy. In the stereoscope a false conception of depth is obtained by viewing two slightly dissimilar images through convex prisms, base in, which relaxes the accommodation and convergence. In reading, the adept does not recognize letters, or even words, individually but assembles them into groups, five or six to the line.

Chas. A. Bahn.

Mata, Pedro. A Case of erythropsia. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1946, v. 6, May, pp. 436-441.

For about two weeks a boy, 10 years old, had noticed that everything became red for about a minute several times a day. During the attack the patient closed the eyes so strongly that a marked blepharospasm was produced. The vision, fundus, and visual fields were normal. All the laboratory tests were negative. The erythropsia was attributed to vascular spasm of the Sylvian and posterior cerebral arteries, which produced irritative hallucinations of the optic pathway or cerebral cortex.

Pascal, J. I. **Ophthalmic calculations by the "dam" method.** *Brit. Jour. Ophth.*, 1947, v. 31, July, pp. 424-426.

Mathematical formulas for the calculation of lens surface power of all thin and of most thick lenses are briefly presented. The "dam formula is the general formula for surface power and is properly written as $D = \frac{A}{M}$. D is the power in diopters, A is the difference between the index of refraction of the second medium and the first, and M is the curvature in metrecs. (A metrec is the unit of curvature and is the ration of lens power expressed in its focal length and its radius of curvature). Thus, to estimate the power of the anterior surface of a cornea having a radius of 8 mm. and an index of 1.376 the formula is applied: $D = \frac{1.376 - 1}{8 \text{ mm.}}$

$$1 = 0.376) \times \frac{1000 \text{ mm.}}{8 \text{ mm.}} = 47. \text{ Or to}$$

estimate the D of the posterior surface of a cornea having a radius of 6.8 and the index of the aqueous is 1.336: $D = \frac{1.336 - 1.376}{6.8}$

$$1.336 - 1.376 \times \frac{1000}{6.8} = -5.88. \text{ The}$$

same formula applies to contact lenses and also to thick spectacle lenses where the sum of the powers of the two surfaces becomes the power of the lens.

Morris Kaplan.

Pfister, A. **A chart for the objective determination of the visual acuity.** *Ophthalmologica*, 1947, v. 113, June, pp. 344-364.

For a number of years H. Goldmann (*Ophthalmologica*, 105:240, 1943) and Pfister have been engaged in studies of the optokinetic nystagmus as a means of estimating the true visual acuity (the minimum separabile) in malingerers. Pfister now describes the many "complications" encountered and the final

method evolved as the result of those complications. The cessation of the optokinetic nystagmus upon reduction of the nystagmus-eliciting pattern below the minimum separabile is the principle of the method. The moment of cessation of the nystagmus is determined by observation of a large episcleral vessel with the ophthalmoscope and a +10D lens. The examinee who is given no information concerning the nature of the test, is asked to look at a checkerboard, black and white pattern, which describes rhythmic up and down movements against a gray background. If the movements of the pattern elicit a definite vertical pendulum nystagmus, the moving checkerboard is moved farther away from the examinee until the nystagmus stops. The refractive error must be accurately corrected with glasses. The observation with the ophthalmoscope must be conducted in such a way that no light falls into the pupil and that there is no interference with the patient's viewing the chart. The aphakic eye does not lend itself to this test because of its low depth of focus. In a few perfectly normal, emmetropic (non-malingering) individuals the nystagmus could not be elicited. There is surprisingly good correlation between the subjective and the objective visual acuity in patients who admit their true acuity.

Thomson, L. C. Binocular summation within the nervous pathways on the pupillary light reflex. *J. Physiol.*, 1947, v. 106, March 15, pp. 59-65.

It has been shown that the degree of constriction of the pupil which results from the stimulation by light of the retina of a single eye was significantly less than that obtained when both eyes were stimulated.

This binocular summation was equivalent to that obtained by increasing the area of the stimulating flash between two and four times and observing with a single eye throughout.

This binocular summation does not appear to be influenced by cerebral cortical activity. The position of the summation within the nervous pathways is discussed.

Theodore M. Shapira.

Tirelli, G. High hypermetropia. *Rassegna Ital. d'Ottal.*, 1947, v. 16, March-April, pp. 85-92.

Tirelli reviews the literature concerning high degrees of hypermetropia and reports the case of a six-year-old boy who had 16 diopters in the right eye and 17 in the left. The partially corrected vision was 2/10 in the right and 1/10 in the left eye. Ophthalmoscopically the only changes observed were

pseudo-neuritis and slight tortuosity of the retinal vessels. Eugene M. Blake.

Wald, George. **The chemical evolution of vision**, The Harvey Lectures, 1945-1946, Series 41, pp. 117-160.

The chemical evolution of vision is traced by the use of the knowledge that carotenoids play a major part in photoreception in plants and animals. The light stimulus, which causes molds and higher plants to bend and show other orientation, is absorbed by carotenes and xanthophylls. These pigments with another carotenoid astaxanthin, are found at the eye spots of certain green flagellates.

Arthropods and molluscs have image forming eyes but cannot synthesize carotenoids, and photoreception is dependent upon vitamin A₁ and retinene₁. Fresh water vertebrates (or animals that spawn in fresh water) have the porphyropsin system of the rods based on vitamin A₂ and retinene₂.

Euryhaline fish (which as adults can tolerate fresh water or salt water) possess both the rhodopsin and porphyropsin systems. The amphibia also have both the rhodopsin and porphyropsin systems. The bullfrog during metamorphosis transfers from the porphyropsin to the rhodopsin system.

Iodopsin is found in vertebrate cones. It is a carotenoid-protein closely related to the rod photopigments. From the human macula a pigment xanthophyll has been isolated, showing that human foveal vision depends on an intact carotenoid. (13 figures.) H. C. Weinberg.

4

OCULAR MOVEMENTS

Anderson, J. Ringland. **Ocular vertical deviations**. Brit. Jour. Ophth., 1947, Monograph Supplement XII.

This monograph presents a study of vertically-acting ocular muscles and includes statistics on a series of 402 patients with horizontal and vertical defects of concomitant and paralytic types. The literature is reviewed. Methods of complete examination are fully described. It is emphasized that the coordinated movements of the eyes, and the compensatory movements of the head must be carefully studied. Only an exact diagnosis with accurate interpretation can lead to the correct treatment.

For the measurement of diplopia and the primary and secondary deviations the screen test is recommended. Anomalies of the vertical rotators, especially the inferior oblique are found more frequently than is usually recognized. In concomitant convergent strabismus an overacting inferior oblique muscle was present in over 30 percent, and in an additional 25 percent, paresis of at least one superior muscle was present. Combined with the horizontal defects these figures show that there are few cases of simple concomitant strabismus.

The vertical range of fusion is small and both poorly controlled and little used; thus a small vertical error readily becomes a tropia. Examination usually reveals a paresis or overaction in a vertical imbalance. It is important to distinguish between primary overactions and secondary overactions in vertical rotator pareses. Palsies of the vertical rotators are complete in that there is no response to cortical, subcortical, vestibular or other stimuli. In supranuclear ocular palsies the fibers are often affected by disease as they pass through the brain stem.

Frequent causes of ocular paresis are twilight sleep, obstetrical forceps, and

motor vehicle accidents. Recovery is the rule, although it is somewhat less for vertical than for horizontal palsies. Orthoptic training may play an important part in the treatment.

In the surgical treatment of vertical disorders three principles of correction are considered. These are the strengthening of the paretic muscle, weakening of the overacting contralateral synergist, and weakening the contracture of the ipsilateral antagonist. Vertical defects associated with concomitant strabismus may decrease or cease after the horizontal deviation has been corrected.

The author voices a need for the reporting of the results of exact findings in large series of cases to remove contradictory opinions from the literature. (37 illustrations.) O. H. Ellis.

Dering, S. A. Post-contusion ophthalmohyperkinesis. *Oftal. Jour.* (Odessa), 1946, pt. 3, pp. 40-42.

In some patients with a history of brain contusion Dering noticed a pronounced convergence, without other visual disturbances, which lasted during the period of examination, and disappeared as the examination was concluded. Two patients had a spasm of convergence, which produced a myopia of four diopters in one eye, and eight in the other, associated with transitory spasm of convergence and blephrospasm. The neurologic diagnosis in these two cases was chronic post-traumatic encephalitis, with muscle spasm. Persistent blephrospasm was another symptom frequently encountered in this group of patients. These symptoms are attributed to an irritation of the nuclei of the third nerve in the floor of the aqueduct of Sylvius, producing an involuntary, abnormal

tonic or clonic contraction of the innervated muscles. Ray K. Daily.

Fink, W. H. Anatomical variations in the attachment of the oblique muscles of the eyeball. *Trans. Amer. Acad. Ophth.*, 1947, May-June, pp. 500-513.

Surgery of the oblique muscles is the least understood and least standardized portion of ocular muscle surgery. This is partly due to normal and abnormal variation of insertion and size of the oblique muscle tendons. In this study of 100 specimens, variations, especially of the tendon, are described in detail. The inferior oblique shows greater anatomical uniformity than the superior oblique. Pareses, contractions and spasms of these muscles are frequently confused with anatomical variations. It is important to note the closer nasal insertion of the superior rectus in reattaching it in surgery involving the underlying superior oblique. As an anatomical landmark the overlying superior rectus tendon is preferable to the trochlear process of the superior oblique. Variations in the fascial sheath which connects the inferior oblique and the inferior rectus (ligament of Lockwood) frequently determine the results of oblique muscular surgery. The inferior oblique is best operated upon at its insertion rather than at its bony origin. The posterior edge of the insertion of the inferior oblique extends to within two millimeters of the optic nerve; as it is usually muscular and has a very short tendon, and it should be severed as close as possible to the eyeball. In the reattachment of severed muscles two sutures rather than one should be used to create as broad a line of contact as possible, and the direction of muscle fibers should not be altered.

In high myopia the position of the inferior oblique is more posterior.

Chas. A. Bahn.

Heinonen, Oscar. Birth injury as a cause of strabismus. *Acta Ophth.*, 1947, v. 25, pt. 1, pp. 19-28.

The investigation was based on the study of 84 cases of strabismus, in patients whose parturition histories were available in the hospital where they were born, 75 cases in patients whose histories were obtained from their parents, and 29 cases from an institution for feeble-minded. This material is analyzed with reference to the weight at birth, abnormal fetal positions, surgical procedures for delivery, prolonged parturition, the number of first-born infants and of twins, frequency of feeble-mindedness, symptoms of trauma in the newborn, and diseases of childhood. Because of the great mortality of infants with severe birth trauma or born prematurely a history of these facts is encountered in only about 10 percent of patients with strabismus. The author has the general impression however that mild birth injuries are an important factor in the etiology of strabismus, and that a history of strabismus in the family and of a difficult parturition are frequently encountered together. It is probable that birth trauma is the exogenous factor that is effective in the presence of the hereditary factor, as in other cerebral lesions. Two brief histories of strabismus in twins are reported, to illustrate the two etiological types of strabismus. In one pair of twins with intermittent strabismus, hyperopia and astigmatism, there was a history of strabismus in the family, and of a prolonged spontaneous parturition. Here the etiology is considered chiefly endogenous. The other twins had con-

vergent strabismus with emmetropia, a history of a difficult parturition, but no family history of strabismus; here the strabismus is attributed to the birth trauma.

Ray K. Daily.

Henderson, J. W. Optokinetic and other factors modifying vestibular nystagmus. *Arch. of Ophth.* 1947, v. 37, April, pp. 459-471.

Vestibular postrotational nystagmus is capable of modification by optokinetic nystagmus. In most cases postrotational response is abolished by repeated daily rotation. This suggests that cortical influences are dominant over those of the vestibular level. There appears to be a poststimulus persistence of optokinetic rotational nystagmus which is effective in reducing postrotational response.

Variability of response has been shown to be the expected finding in the higher forms which possess a well differentiated cerebral cortex. This tends to render less valid work which has been done in lower species whose response is mainly reflex in type. This also supports the accumulating mass of evidence which invalidates the Bárány test as a precise diagnostic aid.

John C. Long.

Joly, J. P. Considerations on the "myocampter." Hypocorrection and hypercorrection in strabismus. *Arch. d'Ophth.*, 1947, v. 7, no. 1, pp. 51-59.

The author discusses muscle-shortening procedures, particularly tucking procedures, and describes his use of the "myocampter" and clamp. He advocates complete tenotomy guarded by suture which is adjusted postoperatively according to the state of the correction. He advocates hypocorrection for convergent strabismus with amblyopia,

and hypercorrection for divergent strabismus with amblyopia, the latter because of the natural tendency of an amblyopic eye to diverge. He has entirely abandoned the operation of advancement. Phillips Thygeson.

Kramer, M. E. The orthoptic treatment of the vertical motor anomalies. *Amer. Jour. Ophth.*, 1947, v. 30, Sept., pp. 1113-1123. (1 table, 1 figure, 16 references.)

Márquez, M. Physiologic explanation of the law of Hering in connection with double innervation of the internal rectus muscle of the eye. *Anales de la Soc. Mexicana de Oft.*, 1947, v. 5, Jan.-March, pp. 3-12.

With three excellent diagrams, the author restates, somewhat revised, his views with regard to conjugate and disjunctive movements of convergence and divergence. He postulates double innervation of the internal rectus muscle both for convergence in association with the internal rectus of the other eye and for adduction associated with the external rectus of the other eye. He confirms Hering's law of equal innervation for the two eyes for each class of movements. (References.)

Prangen, A. deH. Some observations on the surgical treatment of the extraocular muscles. *Amer. Jour. Ophth.*, 1947, v. 30, Sept., pp. 1161-1168. (16 references.)

Rigg, J. P. Operative technic for external and internal strabismus. *J. Internat. Coll. Surgeons*, 1947, v. 10, Jan.-Feb., pp. 63-71.

After a brief review of the principles of the physiology of binocular coordina-

tion and a description of some of the surgical procedures for the relief of strabismus, the author describes his own operation, the advanced tuck. By means of a suture passed through the tendon of a lateral rectus muscle 6 mm. behind its insertion, this part of the tendon can be advanced to the limbus and anchored there. The tendon has been folded on itself and an additional suture through the junction of muscle and tendon is placed for scleral anchorage. A Tucker or a Berens tendon forcepts is used in the folding of the tendon. F. H. Haessler.

Rose, A. T., and Pritzker, S. Paralysis of the abducens nerve following spinal anesthesia. *New England J. Med.*, 1947, v. 237, July 10, pp. 52.

A case of unilateral paralysis of the abducens nerve after spinal anesthesia is reported. Recovery was practically complete in three weeks. The onset of symptoms varies from three to 21 days and is usually preceded by headache, dizziness, stiff neck and photophobia. The paralysis is usually bilateral and is accompanied by diplopia. Recovery takes place in a few weeks or months and is usually complete.

F. H. Haessler.

Savitsky, N., and Winkelman, N. W. Cogwheel phenomenon of the eyes; its clinical significance. *Arch. Neurol. and Psychiat.*, 1947, v. 57, March, pp. 362-368.

The authors state that the occurrence of the cogwheel phenomenon during pursuit movements of the eyes is abnormal, and that its presence indicates the existence of organic disease of the brain. It has been seen most strikingly with chronic encephalitis and other organic diseases.

The authors have observed the cog-wheel phenomenon of the eyes with diphenylhydantoin and bromide poisoning.

The phenomenon has proved of diagnostic value especially in atypical cases of chronic encephalitis and in cases of head injuries. Theodore M. Shapiro.

Sheppard, E. W. Discussion of Miss Kramer's paper. *Amer. Jour. Ophth.*, 1947, v. 30, Sept., pp. 1124-1127. (3 figures.)

Soria. Marcus Gunn phenomenon and voluntary nystagmus. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1947, v. 7, April, pp. 325-334.

Soria reports the case of a 26-year-old man with a left-sided partial ptosis, a Marcus-Gunn phenomenon, and voluntary nystagmus. The nystagmus was horizontal, rapid, of moderate amplitude, and not exceeding forty seconds in duration; the patient initiated it by looking down. The literature on both of these rare phenomena is reviewed. Of the various theories proposed to explain the Marcus-Gunn syndrome, Soria accepts that of Marquez, who believes that the phenomenon represents an exaggerated form of normal synerism between the movements of the mouth and the lids. He sides with Weekers in attributing the genesis of voluntary nystagmus to a cortical excitation, rather than to a cortical inhibition, as is believed by Wilbrand. (5 illustrations.) Ray K. Daily.

Swan, K. C. Esotropia following occlusion. *Arch. of Ophth.*, 1947, v. 37, April, pp. 444-451.

Four cases of esotropia that developed during periods of monocular occlusion are reported. It seems that

spontaneous recovery of single binocular vision is not to be expected from this uncommon, but serious, complication of a commonly used procedure. Treatment should be immediate; otherwise, the deviation tends to increase and the amplitude of fusional movements to decrease, and suppression is likely to develop.

A latent convergent tendency seems to be the condition underlying development of esotropia from occlusion; therefore, in the presence of esophoria or uncorrected hyperopia prolonged monocular occlusion for diagnostic or therapeutic purposes should be used with caution. In the reported four cases, a damage suit was instituted in three. In the treatment of unilateral amblyopia in patients with single binocular vision, lacquering the spectacle lens to reduce visual acuity in the better eye is suggested as safer than total occlusion because binocular vision is maintained. John C. Long.

Wolff, E., and Hefferman. A note on the position of the eye in a third nerve palsy. *Brit. Jour. Ophth.*, 1947, v. 31, July, pp. 427-428.

This very brief case report is presented to call attention to the fact that in oculomotor nerve paresis, the eye looks directly to the side because of overaction of the external rectus and not outward and downward. The superior oblique muscle is unable to depress the eye in extreme abduction.

Morris Kaplan.

CONJUNCTIVA

Alagna, Gaspare, and Faraone, Giuseppe. Development of subconjunctival hemorrhages. *Riv. di Oftalm.*, 1946, v. 1, Nov.-Dec., pp. 657-670.

Extravasations of blood in the skin show color changes different from those observed on subconjunctival hemorrhages; 23 patients were studied to explain this difference. Five of them had hemorrhage with trauma, in six the cause was unknown, and in 12 the hemorrhage was experimentally induced by subconjunctival injection of one to two blood droplets of the patients own blood drawn immediately before the experiment. In this latter group, the blood deposit appeared dark red in the center, and pink in its periphery where biomicroscopy revealed irregularly distributed red cell groups. Twenty-four hours later, the diameter of the blood deposit was greater than after the injection, and biomicroscopically fine absorption lines become visible, forming a network of subepithelial radial channels, the conjunctival lymph vessels. After two and three days, the blood patch was still somewhat larger, pink in color and its borders hazy. At that time, yellowish lines were visible along the vessels, particularly the veins, easier to see at the periphery of the blood deposit. Later on, the color of the blood differs according to the location of the deposit. If it is situated in the exposed area of the bulbar conjunctiva, it changes from pink to yellow and in or near the fornix the color turns from pink to greenish. On the third and fourth day, the blood cells show changes in shape when examined with the corneal microscope and finally only granules of a yellowish red color remain. After 20 and more days, brownish granules are found near the vessel walls. In the two other groups, of traumatic and spontaneous hemorrhages, similar observations were made. The traumatic hemorrhages seemed to spread more rapidly, tortuosities and

partial interruptions of vessels were seen, aneurysmatic dilatations were found in some capillaries, and a granulated current with occasional "emptying" of the capillaries was observed.

The injection of blood under the conjunctiva of each eye of two dogs followed by closure of the lids of one eye failed to demonstrate that the difference in color is due to exposure. Finally, in two rabbits and in two dogs the lacrimal glands of one orbit were extirpated before the injection of blood. The blood patch looked pink as in human conjunctival hemorrhage only if the lacrimal gland was preserved; in eyes deprived of lacrimal irrigation, the blood patch turned bluish red on the third or fourth day, yellowish green two days later, and disappeared after the ninth day. The authors conclude that the bright red color of subconjunctival hemorrhage results from the formation of oxyhemoglobin; lacrimal fluid is needed to transfer oxygen to the blood deposit and to provide the temperature and hydroxyl-ion concentration essential for the oxygenation.

K. W. Ascher.

Bonazzi, A. Giant conjunctival granuloma from vegetable foreign body. *Rassegna Ital. d'Ottal.*, 1947, v. 16, March-April, pp. 131-136.

The very large granuloma described was observed in a farmer whose left eye was injured at the age of a few months and had been atrophic since then. It was assumed that a vegetable foreign body, plus the irritation of the prosthesis, had excited the formation of the granuloma which was adherent at three points. The histologic sections showed nothing unusual. (3 figures.) Eugene M. Blake.

Goldsmith, J. New modification of the McReynolds transplantation for pterygium. *Arch. of Ophth.*, 1947, v. 37, Feb., pp. 194-198.

In the McReynolds operation, the sutures are passed blindly through the loose subconjunctival tissue to emerge from the conjunctiva. The looseness of the subconjunctival tissue does not predispose to firm adhesions with the head of the pterygium. When the silk sutures are removed on the third to the fifth day after operation, part of the newly-formed adhesion is usually disturbed and broken; and if the retractive pull of the pterygium is sufficiently powerful, it is not long before the neck and the head of the retracted pterygium align themselves in the horizontal meridian to commence invasion of the cornea again.

In the new modification, the pterygium is carefully dissected from the cornea and an incision made along the lower margin of the growth. A narrow tunnel is undermined in the bulbar conjunctiva below. An incision 5 mm. in length, concentric with the limbal curvature, is made into the bulbar conjunctiva and Tenon's capsule and is placed 5 mm. from the limbus and made to connect with the tunnel. The head of the pterygium is brought through the tunnel into the new incision and there under direct observation sutured to the episclera and Tenon's capsule with a 0000 chromic gut mattress suture. The chances of recurrence are reduced to a minimum. It is advisable to employ a traction suture if excessive tension on the head of the pterygium is anticipated.

Marin Amat, M., and Marin Enciso, M. A profuse postoperative hemorrhage following a pterygium operation. *Arch. de la Soc. Oft. Hisp.-Amer.*, 1947, v. 7, April, pp. 389-391.

The authors report a postoperative hemorrhage after a pterygium operation, which assumed such proportions that it almost led to exsanguination, in spite of a compressive bandage, the use of all types of coagulants, and blood transfusion. The patient, a fifty-three-year-old woman, had had bilateral extirpation of the lacrimal sacs without complications three months previously. The pterygium operation with excision of the head was bilateral, and on the right side there was more than the usual bleeding during the operation. On the fourth postoperative day the right eye began to bleed after the bandage had been removed and the hemorrhage was checked by a compressive bandage. The bandage was removed the next day, and the following night the hemorrhage recurred, and continued for 24 hours in spite of all measures to arrest it. Hematologic studies revealed no basis for the bleeding. The authors attribute it to a K hypovitaminosis which resulted from chronic undernutrition.

Ray K. Daily.

Peyrét, J. A. **Vernal conjunctivitis: giant limbal type.** *Arch. de Oft. de Buenos Aires*, 1946, v. 21, Oct.-Nov., p. 309.

The author reports a case of vernal conjunctivitis with unusually large limbal lesions. The diagnosis was confirmed by biopsy. Several methods of treatment were tried unsuccessfully. Finally radiotherapy improved the condition markedly, the improvement persisting throughout a period of observation of nearly five years.

Plinio Montalván.

Radnót, M. **A New oculo-glandular disease.** *Ophthalmologica*, 1947, v. 113, Feb., pp. 106-108.

Four cases of a conjunctival lesion are reported that occurred in patients who had contact with probably diseased poultry 24 hours before the onset of the symptoms. No bacteriological studies were made. The disease is probably caused by a virus. It occurred during an epidemic of "birds' plague" in Budapest (apparently an acute infectious disease of fowl similar to chicken cholera) and was characterized by swelling and hyperemia of the conjunctiva without secretion or corneal involvement, followed 24 hours later by the development of a painful preauricular lymphadenitis. Complete recovery occurred within a week.

Peter C. Kronfeld.

Zewi, M. **Reiter's disease.** *Acta Ophth.*, 1947, v. 25, pt. 1, pp. 47-60.

Ten cases of Reiter's disease in patients treated at the Ophthalmic Clinic of the University of Turku are added to the literature. Whereas those formerly reported all occurred in adult men, six of the patients in this series were women. Two were 15 to 16 years old,

and the others over 20. Seven of the patients presented the characteristic triad of polyarthritis, conjunctivitis, and urinary symptoms, and three had no urinary symptoms, which usually are slight and transient. All patients had arthritis, which healed completely. All patients had a catarrhal conjunctivitis which was the first ocular disturbance. Zewi finds that this conjunctivitis has distinguishing features not recorded heretofore, which are of diagnostic importance. The injection is deeper than in an ordinary conjunctivitis, and one has the impression that an episcleritis covers the visible area of the globe. Ten patients had in addition a superficial keratitis, one a mild optic neuritis, and one a keratitis, iritis, and optic neuritis. All recovered completely. Nine of the patients had had diarrhea before being taken ill. This has been reported before and there appears to be some relation between this disease and intestinal infection.

CORNEA AND SCLERA

Agnello, Francesco. **Herpes virus in the etiology of posttraumatic disciform keratitis.** *Riv. di Oftalm.*, 1946, v. 1, Nov.-Dec., pp. 698-705.

Three cases of a posttraumatic deep corneal lesion are described. The lesion started three to four days after the injury, was unilateral and was associated with decreased sensitivity of the cornea and a tendency to recurrence. These qualities are characteristic of herpes. The injury was considered the precipitating etiologic factor and the basis of medicolegal action. K. W. Ascher.

Allen, J. A. **Antitoxin treatment of staphylococcic corneal ulceration.**

Amer. Jour. Ophth., 1947, v. 30, August, pp. 987-992. (4 figures, 3 tables, 2 references.)

Arjona, J. Giant leproma of the sclerocorneal limbus. Arch. de la Soc. Oft. Hisp.-Amer., 1946, v. 6, May, pp. 491-494.

A female patient, 36 years of age, had a tumor mass of six months duration on the left sclerocorneal limbus. It was a leproma and many Hansen's bacilli were found. The patient also had lepromas in the ears and on the hands.

J. Wesley McKinney.

Bedell, A. J. Cephalosporium keratitis. Amer. Jour. Ophth., 1947, v. 30, August, pp. 997-1000. (5 figures, 20 references.)

Burki, Ernst. Progress in keratoplasty. Schweiz. Med. Wchnschr., 1947, v. 77, May 10, pp. 525-528.

This lecture gives the history of keratoplasty, its indications, present status and various techniques of applying it. Early attempts (1818) at transplanting animal corneas failed. v. Hippel, by introducing the round trephine was able to perfect the operation on man but as he too used animal tissue, he was not successful in obtaining clear transplants. Since 1906, when human tissue was first used, keratoplasty has grown constantly easier and more successful.

Methods of corneal transplants are divided into total and partial. So far total keratoplasty, desirable as it is, has not been successful. Partial keratoplasty is of two kinds, partial lamellar (superficial) and partial full thickness, of which the latter is the one in general use. The source of the transplant may be auto-, homo-, or heterogenous. The latter is no longer used. Autoplastic

keratoplasty is the ideal procedure. A disc 6 to 8 mm. in diameter is cut out of a cornea with clear periphery and rotated so that the clear portion lies centrally. Healing leaves the cornea clear, but complications may result from the trepanation. Friede has recently suggested the use of a rectangular flap 3 to 4 by 8 mm. This reduces complications and will probably become the operation of choice.

Most ophthalmic surgeons prefer partial full-thickness homoplasty. A round flap, 3 to 5 mm. in diameter is preferred. Results are best after parenchymatous keratitis, injuries, and hereditary degenerations, poorest when there is anterior synechia or symblepheron or scarring from abscess or acid burns. Eyes with increased intraocular pressure are completely unsuited. The degree of injury is more important than the kind. Scars with anterior chamber intact are successfully replaced in 70 percent of cases, scars with anterior synechia in 20 percent. In complete leucoma the operation always fails. The degree of remaining visual acuity and age of patient are not decisive factors. Young children are less benefited than older individuals.

In homoplasty the donor material may be living cornea, surviving cornea, or killed cornea. The first can be available only in a very large clinic. The surviving cornea taken from patients recently dead of general disease is the material of choice. Eyes of older individuals are more suitable than those of the very young. The entire eye may be removed or pieces of cornea may be taken by trepanation. The material should be kept in a moist chamber at 4 to 6 degrees and may be thus stored for 10 to 12 hours. Transplants will remain clear for weeks if put into liquid paraffin, whereas salt solution

and other media quickly cause swelling and clouding. Tissue fixed in formalin will heal in, but always becomes cloudy later. Clouding is apt to occur eventually in many cases, and not until after eight months can one be certain that a transplant will remain clear. The factors causing late clouding are still unknown. Some believe the transplanted tissue remains and adapts itself as foreign tissue, others think the transplant is gradually replaced by the tissue of the host. Tissue regeneration unquestionably takes place since death and replacement of cells takes place constantly in all tissues.

B. T. Haessler.

Davidson, Alan. Primary lipid dystrophy of the cornea. *Arch. of Ophth.*, 1947, v. 37, April, pp. 433-443.

A case of primary lipid dystrophy with hypercholesteremia in a 61-year-old negro is presented. The patient has been followed for 21 months, and the lesion in the left eye has progressed steadily and asymptotically without evidence of inflammation.

A corneal transplantation was done on this eye, and pathologic studies of the transplant and of biopsy specimens of the cornea of both eyes revealed marked deposition of fatty globules in both corneas. Doubly refractile cholesterol crystals were seen in the epithelium of the left eye. The clinical characteristics of this condition are discussed.

John C. Long.

Fox, Sidney A. Removal of deeply embedded foreign bodies from the cornea. *Arch. of Ophth.*, 1947, v. 37, Feb., pp. 189-193.

Deep corneal foreign bodies may be removed by means of a corneal flap made with a Ziegler discission knife. The flap is fashioned by means of two

incisions meeting at an apex pointing toward the center of the cornea and containing the foreign body between them. The incisions are beveled toward each other, so as to approach the foreign body more closely. After sufficient depth has been attained, the corneal flap is folded back on its base and the foreign body exposed and removed. Rust stains may be curetted. The corneal flap is patted back in place with a spatula. Six illustrative cases are described.

John C. Long.

Franceschetti, S., and Babel, J. Histologic examination of a transparent corneal implant. *Ann. d'Ocul.*, 1947, v. 180, March, pp. 142-146.

Exactly how transparent corneal implants remain viable is not understood. One half of an eye containing a corneal graft which had been transparent during six years was imbedded in paraffin and sectioned longitudinally; the other half was stained with silver and cut frontally for better study of the corneal nerves. Sections showed that Bowman's membrane was present in the implant but not in the host. Descemet's membrane was present both in the host and the implant but was interrupted at their junction. No new vessels were observed in the implant and the stromal layers were continuous with those of the host. Numerous nerves which branched dichotomously were observed in the recipient cornea. Some of the nerves on passing toward the implant made a loop at its border and then entered the recipient cornea parallel to the implant margin. The nerves in the graft were subepithelial.

The primitive structure of the transplant was preserved. Cellular elements pass from the host into the graft. Nerve innervation is apparently secondary to vascularization. Nerve filaments in the

epithelium possibly have a trophic action essential to the physico-chemical exchange which is necessary in maintaining corneal transparency. (7 figures, 7 references.) Chas. A. Bahn.

Katzin, H. M. The preservation of corneal tissue by freezing and dehydration. *Amer. Jour. Ophth.*, 1947, v. 30, Sept., pp. 1128-1134. (1 table, 23 references.)

Krawicz, T. The reticulo-endothelial system of the cornea. *Brit. Jour. Ophth.*, 1947, v. 31, July, pp. 421-423.

To investigate the colloidoptic properties of corneal cells, that is, their permeability to colloidal substances, various dyes were dropped into the conjunctival sac of 30 rabbits for 50 days.

Ten rabbits were similarly treated with solutions of colloidal silver. In microscopic sections the dyes were found in all layers of the cornea which simply acted as a semipermeable membrane between the dye and the anterior chamber. The silver deposits were found intracellularly within the stromal cells and more abundantly within the structure of Descemet's membrane. The author concludes that the corneal stroma cells are wandering cells in a state of rest which means that they correspond to prohistiocytes and that they do not differ functionally from the fundamental components of the reticulo-endothelial system.

Morris Kaplan.

Langer, Z. M. Therapeutic keratoplasty in purulent keratitis. *Oftal. Jour. (Odessa)*, 1946, pt. 3, pp. 34-36.

This is a report of 12 apparently hopelessly lost eyes with extensive traumatic purulent keratitis, with visual acuity ranging from faulty light projection to hand movements, treated by keratoplasty. In two fresh cornea

was used for transplantation, and both eyes were lost. In ten eyes preserved cornea was used, and the final results were form vision in three, hand movements in one, and light perception in six. Regression of the inflammatory phenomena was apparent in two to three days after the operation. The postoperative course was complicated in 9 eyes by anterior synechia and secondary glaucoma. A prophylactic iridectomy, performed while the eye was acutely inflamed, was always beneficial. The curative effect of the transplant is believed to be due to its content of biogenic stimulators. The resulting corneal leucoma can be dealt with later by an optical keratoplasty.

Ray K. Daily.

Manschot, W. A. Blood staining of the cornea. *Ophthalmologica*, 1947, v. 113, April, pp. 203-214.

Four eyes with blood staining of the cornea became available for histologic examination. In one eye the staining occurred as a result of an obstruction of the central retinal vein with secondary glaucoma; in the other three eyes the staining developed after severe trauma. In two of the eyes the staining had been present only for a few days, in the other two eyes for several months. In the histologic picture different stages of the process can be distinguished. The first stage is characterized by the presence of the blood as an amorphous mass between the lamellae. After a few days this amorphous mass takes on a granular form, and then, apparently as the result of absorption from these interlamellar granules, the well-known highly refractile bodies of blood staining develop within the lamellae (second stage). This form of blood staining can last very long. The opaque disc in the

center of the cornea becomes smaller as time goes on, but a small central opacity is the usual permanent result of blood staining. The author has studied histologically the pigment particles that remain within the corneal corpuscles and found them to contain iron as well as fat (hemosiderin as well as lipofuscin). In a fifth (injured) eye the author was able to determine the chemical nature of the highly refractile bodies. After fixation in saturated mercury bichloride, he subjected the sections to tryptic digestion at 37° centigrade. Within seven days the refractile bodies disappeared from the sections which proves that they consist of proteins, apparently the crystalline form of the protein part of the hemoglobin molecule. Peter C. Kronfeld.

Nataf, R., and Fontan, P. Hereditary familial megalocornea. *Ann. d'Ocul.*, 1947, v. 180, May, pp. 267-272.

In a 20 year old male, both corneas were 14 to 16 mm. in diameter, globular and transparent and associated with iridodonesis. Vision could be corrected to 7/10 in each eye. The fields and color vision were normal. Embryotoxon was observed in each eye and in the right there was opacification of the lens nucleus, slight coloboma of the lens above, and partial absence of the zonula. The anterior chamber angle was free but distended. In both eyes the tension was 25 mm. Hg. No apparent endocrine disturbance existed, and the blood Wassermann reaction and chemical test of the blood were negative. Megalocornea existed in the maternal grandfather and in one brother. Chas. A. Bahn.

Pascheff, C. Further research on *pannus follicularis trachomatosus*. *Amer. Jour. Ophth.*, 1947, v. 30, August, pp. 1001-1004. (4 figures, 8 references.)

Peyret, J. A. Familial corneal dystrophies. *Arch. de Oft. de Buenos Aires*, 1946, v. 21, Aug., p. 205.

Two cases of Groenow's corneal dystrophy in mother and son are reported. In the first, a nuclear cataract was extracted from the right eye without complications. The vision improved to 1/10 with correction.

The literature on the subject is briefly reviewed. (Illustrations, bibliography.) Plinio Montalván.

Sagher, F., and Miterstein, B. Effect of Grenz rays on leprous infiltrates. *Arch. of Ophth.*, 1947, v. 38, July, pp. 78-88.

Grenz rays were applied to lepromatous changes in the anterior segments of the eyeball in six patients. Since it was obvious, on the basis of experience with irradiation of the skin, that only large doses would be able to produce an effect, three practically sightless eyes were chosen for exposure to these rays. In all three patients the lepromas undoubtedly became reduced in size or disappeared completely.

When the Grenz rays were employed on the eyes of three additional patients which presented lepromas with fairly good vision, two eyes exhibited a favorable response, whereas in the third the lepromatous part which was irradiated became quiescent, or even slightly flatter, but the surrounding parts presented rapid growth of new lepromas.

The voltage of the rays used ranged from 6 to 14 kilovolts, which is equivalent to half value layers of 0.021 to 0.031 mm. of aluminum. The most effective doses applied at one sitting were from 700 to 1,200 r, and the total amount varied from 5,500 to 11,600 r. These large doses could be applied safely to the external tissues of the eye because the sensitivity of such tis-

sues to rays is lower than that of the skin. No damage to the cornea, lens or deeper structures of the eye was noted, so far as this could be determined on the basis of observations extending over a period of two to four years.

Schmidtke, R. L. **Hypovitaminosis A in ophthalmology.** Arch. of Ophth., 1947, v. 37, May, pp. 653-667. (See Section 17; Systemic disease and parasites.)

Shepard, E. M. **Relief of episcleritis by histamine diphosphate.** Amer. Jour. Ophth., 1947, v. 30, July, pp. 907-909.

Sjønøft, Finn. **A case of interstitial keratitis after a gluteal abscess.** Acta Ophth., 1947, v. 25, pt. 1, pp. 73-80.

The gluteal abscess developed as a result of a milk injection given for a slight bilateral iridocyclitis, and cultures of the abscess showed hemolytic streptococci. Thirteen days after the milk injection a bilateral symmetrical corneal affection developed, which began near the limbus above, and gradually spread toward the center, with disseminated grayish interstitial foci. Myocarditis and pulmonary abscess developed on the day following the onset of the keratitis. In the course of 54 days, during which several fresh corneal foci appeared, the infiltrates disappeared, becoming hazier and receding towards the limbus. The patient was dismissed with residual posterior synechia, and small deep peripheral corneal opacities with deep vascularization. It was thought that the patient had a metastatic parenchymatous keratitis, secondary to a sepsis caused by the streptococcus. Where the streptococci originated remained undertermined. It

is not believed that it originated in the milk, because another patient, who was injected with 10 cc. of the same portion of milk suffered no complications.

Stanbury, F. C., and Wadsworth, J. A. C. **Surgical technique of corneal transplantation in rabbits.** Amer. Jour. Ophth., 1947, v. 30, August, pp. 968-978. (6 figures, 19 references.)

Valdecasas, Pedro G. **Keratitis caused by an alcoholic solution of chirimoya seeds.** Arch. de la Soc. Oft. Hisp.-Amer., 1947, v. 7, April, pp. 379-380.

Valdecasas believes that the cases of keratitis reported by Romero as caused by alcohol fumes from a shampoo, are actually due to the caustic effect of chirimoya seeds, commonly steeped in alcohol, and believed to be effective against head lice. At present alcohol is commonly used as a constituent of face lotions and colognes, and it seems improbable that it alone could produce as pronounced corneal damages as was found in Romero's cases. It is more probable that the offending agent was the macerated seeds; the greater involvement of the center of the cornea is attributed to the lesser humidity in that area, which diminishes its capacity to neutralize the caustic effect of the alcoholic solution of these seeds.

UVEAL TRACT, SYMPATHETIC DISEASE, AND AQUEOUS HUMOR

Arentsen, Juan. **A case of sympathetic ophthalmia cured with penicillin.** Arch. Chilenos de Oft., 1946, v. 2, July-Oct., pp. 249-255.

The author has devoted attention to subconjunctival treatment with peni-

cillin, and arrives at the conclusion that the doses employed were in many cases too low. When the dose was carried above 1,000 or 1,500 Oxford units, the injections became very painful, so preliminary injection of 2-percent novocaine solution subconjunctivally was resorted to, and in this way it was possible to raise the dose of penicillin to 5,000 units. The author regards the best combination for subconjunctival injection as one part of 4-percent novocaine solution with two parts of physiologic sal solution that contains 5,000 Oxford units of penicillin per cubic centimeter. He reports the favorable outcome of such treatment in a sympathizing eye in which the involvement persisted for some time after removal of the exciting eye.

W. H. Crisp.

Barahona, B. Ectropion of the uvea. Arch. de la Soc. Oft. Hisp.-Amer., 1946, v. 6, May, pp. 494-496.

A case of congenital ectropion of the uvea in a girl five years old is reported. The ectropion covered a large part of the iris stroma. The eye showed no other anatomic or function anomaly.

J. Wesley McKinney.

Carusi, E. A new procedure for the treatment of iridodialysis. Rassegna Ital. d'Ottal., 1947, v. 16, March-April, pp. 93-97.

The procedure described consists of four steps. The conjunctival flap is dissected at the site of the iridodialysis; a keratome is introduced one half millimeter from the limbus to make an incision slightly less than the width of the dialysis; the iris is caught on a Jaeger hook and drawn out of the wound for one millimeter. The iris is then transfixated with a double-armed suture of hair by passing the needles through the conjunctival flap and tying

the knot. The iris is gently replaced so that the pupil is as nearly round as possible. Finally, the conjunctival flap is sutured with interrupted silk sutures.

Eugene M. Blake.

Dragomiretzki, G. A. Therapy of myopic chorioretinitis with vitreous from preserved eyes. Oftal. Jour. (Odessa), 1946, pt. 3, pp. 32-33.

Dragomiretzki experimented with rectal and subcutaneous injections of autoclaved vitreous of preserved beef eyes. The course of therapy consisted of 10 injections, every other day. The tabulated data of 12 cases show an improvement in visual acuity, and in five patients a 10 to 15-degree widening of the visual fields.

Ray K. Daily.

Gormaz, Alberto. Sympathetic ophthalmia. Arch. Chilenos de Oft., 1946, v. 2, July-Oct., pp. 255-256.

The author reports a case in which sympathetic involvement of the second eye began 56 days after enucleation of the exciting eye. Recovery occurred under sulfathiazole.

W. H. Crisp.

Kholina, A. A. Tissue therapy with the Filatov method. Oftal. Jour. (Odessa), 1946, pt. 3, pp. 29-31.

Kholina reports from Kiev nine cases of severe iritis, which recovered more rapidly than usual, under treatment with injections of extract of leaves of aloes, and implantation of preserved skin.

Ray K. Daily.

Matteucci, P. Sympathetic innervation and the neuro-vegetative regulation of the uvea. (Influence of the cervical sympathetic upon intraocular tension in normal and pathological eyes.) Rassegna Ital. d'Ottal., 1947, v. 16, May-June, pp. 186-198.

The conclusions reached by the author are derived from experiments upon rabbits and from histologic studies of the eyes which were enucleated after the experiments. Interference with the sympathetic nerves provokes oscillations of ocular tenion without modifying the caliber of the choroidal vessels. It also disrupts the physico-dynamic circulatory equilibrium of the blood and aqueous, so that there is altered capillary permeability and retarded reformation of the aqueous after puncture of the anterior chamber. Pigmentary changes were observed in the iris and ciliary processes. (9 photomicrographs.)

Eugene M. Blake.

Morano, M. Detachment of choroid in the course of hypertensive toxemia of pregnancy. *Boll. d'Ocul.*, 1946, v. 25, July-Sept., pp. 379-401.

Systematic observations of the fundus during eclampsia or the pre-eclampsia state, four cases of which are described in detail, lead the writer to believe that the so-called retinal detachment of eclampsia is in reality a detachment of the choroid. The sudden bilateral appearance of dark-gray non-fluctuating protrusions of the retina, always in the lower portion, the lack of retinal tears, and the disappearance of the protrusions after the emptying of the uterus are considered typical differential symptoms. Especially important for the differential diagnosis is the presence of pigment changes at the site of the detachments and the choroidal atrophy as is seen in choroidal detachment after intraocular operations such as cataract extractions and decompressive procedures. The pathogenesis of similar detachments is discussed at length. (Bibliography.)

Melchior Lombardo.

Nyquist, B. Benign course of sympathetic ophthalmia. *Acta. Ophth.*, 1947, v. 25, pt. 1, pp. 9-17.

Four cases of transient sympathetic ophthalmia, designated as such by Meller in 1925, are briefly reported. Three cases followed perforating sclero-corneal injuries, and one a cataract extraction. Two of the eyes were perforated by metallic splinters which entered the eyeball, and were extracted with a magnet, and one cornea was perforated by a piece of wood. All of the sympathizing eyes were free from subjective symptoms and had no ciliary congestion. The diagnosis was based on the presence of a few circulating corpuscles in the aqueous, and one or several small deposits on the posterior corneal surface, found on routine slit-lamp examination. Treatment during the pre-sympathetic stage consisted of atropin, pyrogenic agents, and rest. After the onset of sympathetic ophthalmia mercury ointment, neoarsphenamine, X-ray therapy, reduced illumination, and prolonged bed-rest were added. Of three enucleated eyes, histologic examination was available in two; the sections showed a chronic uveal inflammatory process, without typical nodules or giant cells. It is believed that intensive therapy arrested the development of the anatomic changes typical of sympathetic ophthalmia. The question of enucleating the injured eye after the appearance of sympathetic ophthalmia in the fellow eye is discussed, and contrary to the general belief Nyquist holds that such eyes should be enucleated because the inflammatory process in the injured eye may cause relapses of sympathetic ophthalmia in the fellow eye. (4 photomicrographs.)

NEWS ITEMS

Edited by DONALD J. LYLE, M.D.
904 Carew Tower, Cincinnati 2

News items should reach the editor by the 12th of the month

DEATHS

Dr. William Lorne Deeton, Cleveland, Ohio, died July 28, 1947, aged 47 years.

Dr. James Garfield Dwyer, New York, New York, died August 2, 1947, aged 65 years.

Dr. Edwin Baker Goodall, Boston, Massachusetts, died August 6, 1947, aged 65 years.

Dr. John Jacob Gurtov, New York, New York, died July 28, 1947, aged 67 years.

Dr. Joseph Hallock Moore, Huntington, West Virginia, died August 3, 1947, aged 45 years.

Dr. Alpheus Keller Wilson, Jacksonville, Florida, died July 24, 1947, aged 67 years.

MISCELLANEOUS

During September and October, the Department of Ophthalmology, University of Glasgow, held a series of postgraduate lectures. The following papers were read and discussed: "Contact Lenses," Mr. F. Ridley; "Industrial Cataract," Dr. J. D. Fraser; "Pathology and Clinical Aspects of Ocular Glassmembranes," Prof. Arnold Loewenstein; "Some Problems in Ophthalmoscopic Diagnosis," Prof. A. J. Ballantyne; "Ophthalmology in Poland," Prof. W. J. B. Riddell.

SOCIETIES

PRELIMINARY PROGRAM

III PAN-AMERICAN CONGRESS

A tentative program for the III Pan-American Congress of Ophthalmology, at Havana, Cuba, has been announced by the committee.

Sunday—January 4, 1948

8:30 a.m.—Registration

3:00 p.m.—Preparatory Assembly—(business)

5:00 p.m.—Opening of Exposition—(scientific & commercial)

9:30 p.m.—Formal opening at Capitol

Monday—January 5, 1948

8:30 a.m.—Official opening of Scientific Program

12 to 2 p.m.—Lunch

2:00 p.m.—Official subjects of Scientific Program

9:00 p.m.—Formal session—University—(Honoring the Rector of the University of Havana, the Dean of Faculty of Medicine, and the Guest of Honor.)

Tuesday—January 6, 1948

8:30 a.m.—Official subjects of Scientific Program

12 to 2 p.m.—Lunch

2:00 p.m.—Courses—English, Portuguese, Spanish

4:30 p.m.—Exhibits

6:30 p.m.—Reception by the Mayor of Havana

9:30 p.m.—Cuban fiesta

Wednesday—January 7, 1948

8:30 a.m.—Official subjects of Scientific Program

12 to 2 p.m.—Lunch

2 to 4:30 p.m.—Courses—English, Portuguese, Spanish

7:00 p.m.—Reception by the Cuban Medical Federation

9:00 p.m.—Formal session Academy of Science—Gradle Lecture—Prevention of Blindness Medal to Dr. Harry S. Gradle—Award of Pan-American Medals

Thursday—January 8, 1948

8:30 a.m.—Official subjects of Scientific Program

12 to 2 p.m.—Lunch

2 to 4 p.m.—Courses—English, Portuguese, Spanish

4:00 p.m.—Free papers

9:30 p.m.—Pan-American fiesta at the Havana Yacht Club

Friday—January 9, 1948

8:30 a.m.—Official subjects of Scientific Program

12 to 2 p.m.—Lunch

3:00 p.m.—Business meeting

6:00 p.m.—Reception at the President's Palace

Saturday—January 10, 1948

8:30 a.m.—Prevention of Blindness

1:30 p.m.—Lunch at the Jockey Club

2:30 p.m.—Races

9:00 p.m.—President's banquet—(Closing)

ANNOUNCEMENT

BOARD EXAMINATIONS

The American Board of Ophthalmology announces that the written qualifying test will be given on January 14, 1948, in many cities throughout the country. Practical examinations will be given at Baltimore in May, and at Chicago in October. Information may be obtained from Dr. S. Judd Beach, secretary, 56 Ivie Road, Cape Cottage, Maine.

PAN-AMERICAN NOTES

Edited by M. Uribe Troncoso, M.D., 500 West End Avenue, New York

Communications should reach the editor by the 12th of the month.

III PAN-AMERICAN CONGRESS OF OPHTHALMOLOGY

The government of Cuba has extended official invitations to all the governments of America to send representatives to the III Pan-American Congress of Ophthalmology. It is expected that many ophthalmologists will be present, not only from this country, but also from South America and Europe. Sir Stewart Duke-Elder, London, Dr. Bailliant, Paris, Dr. A. Fuchs, China, Dr. Manuel Marquez formerly of Madrid and now of Mexico City, Dr. K. Lindner, Vienna, and Dr. H. Arruga, Barcelona, have promised to attend and read papers. Besides the official reports, 27 free papers have been included in the program. In a special session on January 7th an honor medal of the Pan-American Congress will be presented to Dr. William H. Crisp of Denver and Dr. Manuel Uribe Troncoso of New York.

The meeting of January 10th will be devoted to papers and discussions on prevention of blindness, in which Dr. F. M. Foote from the United States and other directors of similar societies in Latin America will be present. Dr. P. Bailliant, the president of the International Association for the Prevention of Blindness, has promised to attend the meeting.

Fifty courses of instruction given in English, Spanish, and Portuguese are included in the program and will take place on January 6th, 7th, and 8th. Besides the Scientific Exhibition there will be a Technical Exposition and an Exhibition of Ophthalmological Literature. A new departure is the collection of amateur art, curiosities, oil and water color paintings, photographs, sculptures, and other objects of similar nature made by ophthalmologists or their relatives.

The receptions and entertainments will be numerous. The President of the Cuban Republic will receive the members of the Congress in the Presidential Palace and the many social and medical clubs of Havana will be open to all members and their families.

Although no more reservations are available at the principal hotels, the local committee, (Dr. Miguel Branly, Secretary Escuela de Medicina, Calle 25 e I, Vedado, Habana) is arranging to provide new accommodations for late applicants in the smaller hotels and in private houses. A

check or money order for ten dollars (\$10.00) should be sent to the secretary to secure reservations.

GUATEMALAN OPHTHALMOLOGICAL SOCIETY

On August of this year on the occasion of the visit of Dr. Tomas R. Yanes and Dr. M. A. Branly of Habana, the ophthalmologists of Guatemala met and started a society which will work for the advancement of ophthalmology in the country and encourage the education of young specialists. Dr. Branly offered a fellowship in ophthalmology for a student who will attend the courses in Habana University and its Hospital. On the board of the society are Dr. R. Pacheco Luna, president, and Dr. J. Miguel Medrano, secretary.

NECROLOGY

Dr. A. Garcia Miranda, professor of ophthalmology in Granada and then in Salamanca, Spain, one of the most progressive young Spanish ophthalmologists, died recently in Spain, after a professional trip to the United States.

CHILE

At a meeting held on April 5, 1946, the following officers were unanimously elected by the Sociedad Chilena de Oftalmologia: President, Prof. Italo Martini; vice president, Prof. C. Espildora Luque; treasurer, Dr. Rene Contardo; secretary, Dr. Adrian Araya; pro-secretary, Dr. Herman Brink.

ECUADOR

The Sociedad Ecuatoriana de Otorrinolaringologia y Oftalmologia (Quito) has elected the following officers: President, Dr. L. Fernando Lopes; vice president, Dr. Herman Parker; secretary, Dr. A. Carlos Peña; treasurer, Dr. P. Cevallos Jijon.

URUGUAY

The Sociedad Uruguay de Oftalmologia has elected the following officers to serve during 1946-47: President, Dr. Julio A. Sicardi; vice president, Dr. Luis A. Barriere; secretary, Dr. Guillermo Rivas; treasurer, Dr. Ignacio Errea.

COLOR ILLUSTRATIONS—VOLUME 30, 1947

- Plate 1—*Figure 2*. Vesicular cells lying on the posterior capsule freely exposed to the aqueous. *Figure 6*. Anterior subcapsular cataract showing the changing of epithelial cells into fibers and the laying down of intercellular substance. *Figure 25*. A large druselike body under the anterior capsule. The calcified lens is dislocated and turned around in the anterior chamber. Bernard Samuels facing page 1
- Figure 8. A malignant neurogenic melanoma of the conjunctiva which arose from a congenital nevus. Algernon B. Reese on page 548
- Figure 13. A case of cancerous melanosis developing from precancerous melanosis. Algernon B. Reese on page 555
- Figure 14. A case of cancerous melanosis developing from precancerous melanosis. Algernon B. Reese on page 556
- Plate 2—*Figure 1*. Extensive traumatic iridodialysis with repair. Appearance of the eye six weeks after the second procedure. Frank W. Newell facing page 695
- Plate 3—*Figure 5*. Angioid streaks. Early defects and intense stain of Bruch's membrane. Bertha A. Klien facing page 955
- Plate 4. Cross section of optic stalk soon after entrance of axons of ganglion cells of retina. Henry C. Haden facing page 1205
- Plate 5—*Figure 2*. Seborrhic blepharitis of several years' duration with typical coarse greasy scales. This subject also had seborrhic dermatitis of the brows, scalp, and retroauricular folds. *Figure 3*. Lid-margin scrapings from a case of seborrhic blepharitis with associated severe conjunctivitis and keratitis. Joseph S. Gots, Phillips Thygeson, and Morris Waisman facing page 1485

SUBJECT INDEX

Explanation: Numbers in parentheses refer to abstracts

A

- Abduction, congenital deficiency of, (788)
- Aberrations, spherical and chromatic, (783)
- Abscess, gluteal, interstitial keratitis following, (1618)
 - metastatic in osteomyelitis, (529)
 - orbital, fusospirochetal, 1427
 - retrobulbar, 763
 - ring, in Behcet's disease, (795), (837)
- Abstract Department, 222
- Abstracts, (89), (226), (348), (503), (641), (774), (928), (1040), (1186), (1319), (1449), (1594)
 1. General methods of diagnosis, (226), (503), (774), (928), (1186), (1594)
 2. Therapeutics and operations, (227), (504), (775), (928), (1187), (1594).
 3. Physiologic optics, refraction, and color vision, (232), (510), (641), (782), (931), (1191), (1600)
 4. Ocular movements, (238), (517), (643), (786), (933), (1195), (1606)
 5. Conjunctiva, (240), (518), (644), (792), (933), (1198), (1610)
 6. Cornea and sclera, (243), (521), (646), (793), (934), (1040), (1199), (1613)
 7. Uveal tract, sympathetic disease, and aqueous humor, (252), (527), (649), (800), (936), (1042), (1201), (1449), (1618)
 8. Glaucoma and ocular tension, (656), (803), (940), (1043), (1451)
 9. Crystalline lens, (89), (348), (669), (812), (943), (1046), (1461)
 10. Retina and vitreous, (91), (353), (672), (814), (944), (1046), (1319), (1465)
 11. Optic nerve and toxic amblyopias, (104), (364), (676), (820), (1048), (1322), (1470)
 12. Visual tracts and centers, (109), (367), (679), (821), (1049), (1323), (1471)
 13. Eyeball and orbit, (111), (370), (679), (823), (947), (1049), (1325), (1472)
 14. Eyelids and lacrimal apparatus, (113), (374), (681), (828), (950), (1050), (1327), (1472)
 15. Tumors, (115), (378), (682), (832), (952), (1051), (1330), (1475)
 16. Injuries, (115), (379), (683), (833), (952), (1051), (1330), (1476)
 17. Systemic diseases and parasites, (117), (384), (684), (837), (1053), (1333), (1478)
 18. Hygiene, sociology, education, and history, (119), (388), (688), (840), (1057), (1337), (1481)
 19. Anatomy, embryology, and comparative ophthalmology, (121), (840), (1058), (1340)
- Accommodation, after iridocyclitis, (1195)
 - and the estrogens, (1605)
 - in Adie's syndrome, (368)
 - in emmetropia, (516)
 - spasm of, during lactation, (1604)
 - studies on, (235)
- Accommodative astigmatism, 289
- Achromatism of the eye, (234)
- Acrodynia with photophobia, (685)
- Adaptation, dark, (233)
 - campimetry for measuring, (236)
 - rate and threshold gradient in, 705
 - and sulfonamides, (516)
 - tests for, 912
- Adaptometer, direct registering, (512)
- Adenocarcinoma of lacrimal gland, 1020
- Adie's syndrome, (368), (1471)
 - accommodation in (368)
- Adiposogenital syndrome, (684)
- Adrenal, neuroblastoma of, with orbital metastases, 733
- Adrenalin, derivatives, action on eye, (779)
 - mydriatic action, study of, (231)
- Adults, ocular signs of hematoma in, 337
- Advances in care of muscle anomalies, 343
- Africa, iridocyclitis in, (534)
- Air, for locating foreign bodies, 913
 - in cyclodialysis, 1063
 - in ophthalmology, (659)
- Akinesia, (780)
- Alactoflavinosis, ocular manifestations of, (521)
- Albucide therapy, in conjunctivitis, (799)
 - in corneal ulcer, (799)
 - in trachoma, (799)
- Alcohol, retrobulbar injections of, effect, (930)
 - therapy, for blepharoclonus, (375)
 - for herpetic keratitis, (796)
- Alcoholic optic neuritis, (105)
- Alkali burns, (382)
- Allergy, (1602)
 - acquired ophthalmic, 624
 - cause of keratitis rosacea, (936)
 - due to endogenous hormones, (936)
 - due to goldarsenobenzol derivative, (505)
 - due to tears in tuberculous patients, (829)
 - hemorrhagic, and the eye, (1056)
 - iritis from, (528)
 - manifestations of eye, (1336)
 - vascular basis of, (386)
- Aloe-leaf extract, therapy in retinitis pigmentosa, (819)
- Alopecia of eyebrow, (118)
- Aluminum and alloys, effect on eye, (1477)
 - tolerance of eye to, (1478)
- Amaurosis, quinine, (117)
- Amblyopia, alcoholic, (105)
 - ex anopsia, treatment of, 916
 - functional, 1582
 - methyl-alcohol, (105)
 - nutritional, 66, (95), (1322), (1479)
 - quinine, (117), (356), (364), (365)
 - pathogenesis of, (1470)
 - tobacco, (365), (676)
 - toxic, sinusitis in, (117)
 - unexplained, a military problem, (783)
- Amino-acid deficiency in rats, 330
- Amniotic membrane grafts in caustic burns, (251)
- Analgesia, histamine for, (505)

Explanation: Numbers in parentheses refer to abstracts

- Anatomy, applied in eye surgery, (1191)
 embryology, and comparative ophthalmology, (121), (840), (1058), (1340)
 facial nerve, with reference to akinesia, (780)
 parietal and occipital lobes of brain, (121)
 Anesthesia, basal scopolamine-morphine-ephedrine, (1600)
 influence on histamine chemosis in rabbits, (508)
 pentothal sodium, (1599)
 surface with farmocaine, (1596)
 Aneurysm, of carotid, (677)
 ophthalmic symptoms of, (827)
 of cerebral vessels, (789)
 Angioid streaks, (99), (104), 335, 955
 Angioma, of choroid, (529)
 of orbit, (826), (947)
 of retina, 334
 Angiosarcoma, of choroid, (378), (652)
 Angiosclerosis, retinal, (647)
 neuroarteriolar, test in, (675)
 Aniridia, congenital, (1043), 1178
 study of, (531), (533)
 Aniseikonia, (1191)
 diagnostic factors in, 885
 oblique, 1169
 visual education in, (511)
 Anisocoria, posttraumatic, (1451)
 Anomalies, congenital, due to maternal rubella, (122), (1056), (1334)
 due to maternal varicella, (839)
 of lens, (350)
 Antergan therapy, in vernal conjunctivitis, (792)
